**ABSTRACT:** Recent studies have revealed that single-layer transition-metal oxides and dichalcogenides ( $\text{MX}_2$ ) might offer properties superior to those of graphene. So far, only very few  $\text{MX}_2$  compounds have been synthesized as suspended single layers, and some of them have been exfoliated as thin sheets. Using first-principles structure optimization and phonon calculations based on density functional theory, we predict that, out of 88 different combinations of  $\text{MX}_2$  compounds, several of them can be stable in free-standing, single-layer honeycomb-like structures. These materials have two-dimensional hexagonal lattices and have top-view appearances as if they consisted of either honeycombs or centered honeycombs. However, their bonding is different from that of graphene; they can be viewed as a positively charged plane of transition-metal atoms sandwiched between two planes of negatively charged oxygen or chalcogen atoms. Electron correlation in transition-metal oxides was treated by including Coulomb repulsion through LDA +  $U$  calculations. Our analysis of stability was extended to include in-plane stiffness, as well as ab initio, finite-temperature molecular dynamics calculations. Some of these single-layer structures are direct- or indirect-band-gap semiconductors, only one compound is half-metal, and the rest are either ferromagnetic or nonmagnetic metals. Because of their surface polarity, band gap, high in-plane stiffness, and suitability for functionalization by adatoms or vacancies, these single-layer structures can be utilized in a wide range of technological applications, especially as nanoscale coatings for surfaces contributing crucial functionalities. In particular, the manifold  $\text{WX}_2$  heralds exceptional properties promising future nanoscale applications.

## INTRODUCTION

Three-dimensional (3D)  $\text{MX}_2$  (M, transition metal; X, chalcogen atom) compounds constitute one of the most interesting classes of materials and display a wide range of important properties. Their bulk compounds include oxide superconductors,<sup>1</sup> half-metallic magnets,<sup>2</sup> superlubricants,<sup>3</sup> catalysts in redox-based reactions,<sup>4</sup> and solar converters,<sup>5</sup> among others. Some of these compounds have  $D_{6h}$  point-group symmetry and occur in layered structures formed by the stacking of weakly interacting two-dimensional (2D)  $\text{MX}_2$  layers and are specified as 2H- $\text{MX}_2$ . Another type of layered structure known as the 1T structure has  $D_{3d}$  point-group symmetry and is common to several of  $\text{MX}_2$  compounds. Only a few 3D  $\text{MX}_2$  compounds can be stable both in 2H and 1T structures. In addition to 2H and 1T layered structures, some  $\text{MX}_2$  compounds can be stable in one of the 3D structures known as rutile, 3R, marcasite, anatase, pyrite, and tetragonal structures. An extensive review of bulk 3D  $\text{MX}_2$  compounds can be found in ref 6.

Specifically, rutile crystal and thin films of  $\text{CrO}_2$  have been investigated because of their spintronic applications. Tunneling magnetoresistance was initially observed in films of half-metallic  $\text{CrO}_2$ .<sup>7</sup> Electronic and magnetic properties of bulk<sup>8</sup> and epitaxial<sup>9</sup>  $\text{CrO}_2$  have also been investigated theoretically.<sup>10</sup> Single-layer  $\text{CoO}_2$  has played an important role in understanding the superconducting properties of nickel and cobalt

oxide based compounds. In these structures, single layers of  $\text{CoO}_2$  are separated generally by thick insulating layers of  $\text{Na}^+$  ions and  $\text{H}_2\text{O}$  molecules.<sup>1</sup> The high- $T_C$  superconducting properties of these structures arise from the single layer of the  $\text{CoO}_2$  plane. Electronic, magnetic, and optical properties of the cubic pyrite-type  $\text{CoS}_2$  structure have been investigated theoretically,<sup>2,11–14</sup> focusing on the half-metallic properties of this magnet.

$\text{VO}_2$  has various allotropes at different temperatures. For example, at low temperature, a monoclinic (M1) phase occurs, whereas at high temperatures, the rutile metallic phase is favored. By varying the temperature of the system, one can observe the metal-to-insulator transition.<sup>15</sup> The synthesis and characterization of the layered structure of bulk  $\text{VSe}_2$  and its superconducting properties have also been investigated experimentally.<sup>16,17</sup> A recent theoretical study on the electronic and magnetic properties of monolayers of  $\text{VS}_2$  and  $\text{VSe}_2$ <sup>18</sup> concluded that the magnetic properties of these structures can be controlled by applying strain.

The interaction of iron with chalcogens, and specifically with  $\text{O}_2$  molecules, is of great interest, because it involves processes varying from corrosion to oxygen transport in biological

systems. Such materials can also be used as catalysts or catalytic supports in redox-based reactions.<sup>4</sup> FeS<sub>2</sub>, the most well-known compound among Fe-based materials, has been studied extensively. The pyrite structure, the most stable polymorph of FeS<sub>2</sub>, is a crucial compound in materials research.<sup>19–23</sup> Recently, a new method has been put forward and used to synthesize 2D nanowire networks of FeS<sub>2</sub>.<sup>24</sup> Powders of FeS<sub>2</sub> showing rodlike morphologies are attracting considerable interest, because they are promising materials for solar energy conversion. The shape and thermodynamic stability of FeS<sub>2</sub> powders have been investigated using first-principles methods, pointing out the differences between nano- and macroscale properties.<sup>25</sup> FeS<sub>2</sub> nanosheets on iron substrates are also used as photocathodes from tandem dye-sensitized solar cells.<sup>26</sup> FeS<sub>2</sub> pyrite nanocrystal inks are also used in thin-film photovoltaic solar cells.<sup>5</sup> The above brief overview intends to show how comprehensive and diverse the features of MX<sub>2</sub> crystals can be.

On the other hand, advances in nanotechnology have led to the synthesis of novel 2D nanostructures. For example, exceptional properties, such as high carrier mobility, linearly crossing bands at the Fermi level contributing massless Fermion behavior, and perfect electron–hole symmetry that originates from a strictly 2D honeycomb structure, have made graphene an attractive material for future applications.<sup>27,28</sup> Group IV elements, such as Si and Ge, have also been shown to form buckled honeycomb structures with bands linearly crossing at the Fermi level.<sup>29–32</sup> In addition, suspended 2D single-layer BN<sup>33</sup> and, more recently, single-layer transition-metal dichalcogenides MoS<sub>2</sub><sup>34</sup> and WS<sub>2</sub><sup>35</sup> with honeycomb structure have been synthesized. Single-layer NbSe<sub>2</sub> was synthesized only on SiO<sub>2</sub> substrate.<sup>36</sup> Theoretical<sup>37–45</sup> and experimental studies dealing with the electronic structure,<sup>34,40</sup> lattice dynamics, Raman spectrum<sup>46,47</sup> and Born effective charges indicate that single-layer MoS<sub>2</sub> is a nonmagnetic semiconductor displaying exceptional properties. These properties of single-layer MoS<sub>2</sub> and its nanoribbons<sup>41</sup> have been exploited in diverse fields such as nanotribology,<sup>3,48</sup> hydrogen production,<sup>49</sup> hydrodesulfurization,<sup>50</sup> and solar energy production.<sup>51</sup> Whereas the charged surfaces of MoS<sub>2</sub> attain a water-repellant character, specific vacancy defects in MoS<sub>2</sub> can split H<sub>2</sub>O to produce free H<sub>2</sub> molecule as a sustainable energy resource.<sup>52</sup> Most recently, a transistor fabricated from a single MoS<sub>2</sub> layer pointed out features of these materials that can be superior to those of graphene.<sup>53</sup> Whereas graphene is ideal for fast analog circuits, single-layer MoS<sub>2</sub> appears to be promising for optoelectronic devices, solar cells, and light-emitting diodes.

The most recent experimental study by Coleman et al.,<sup>54</sup> which reported liquid exfoliation of MoS<sub>2</sub>, WS<sub>2</sub>, MoSe<sub>2</sub>, TaSe<sub>2</sub>, NbSe<sub>2</sub>, NiTe<sub>2</sub>, and MoTe<sub>2</sub> nanosheets having honeycomb-like structures, motivated us to engage in an extensive analysis of stability to address the question of whether other single-layer transition-metal dioxides or dichalcogenides MX<sub>2</sub> can exist in honeycomb-like structures. In this work, we examined MX<sub>2</sub> compounds (M = Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Nb, Mo, W; X = O, S, Se, Te) to reveal which ones can be stable in 2D suspended, single-layer structure. We took into account two different single-layer structures, namely, honeycomb (H) and centered honeycomb (T) structures; both can be viewed as a positively charged 2D hexagonal lattice of M atoms sandwiched between two hexagonal lattices of negatively charged X atoms. In both H and T structures, instead of forming covalent sp<sup>2</sup> bonding with three neighboring carbon atoms in graphene, each M atom has six nearest X atoms, and each X atom has

three nearest M atoms forming p–d hybridized ionic M–X bonds. Figures 1 and 2 depict 2D single-layer H and T

**Figure 1.** Atomic structure and charge density analysis of 2D single-layer MoO<sub>2</sub> presented as a prototype for MX<sub>2</sub> in the H structure. (a) Top and (b) side views of H structure showing the primitive unit cell of the 2D hexagonal lattice with Bravais lattice vectors  $\vec{a}$  and  $\vec{b}$  ( $|\vec{a}| = |\vec{b}|$ ) and relevant internal structural parameters. Gray and red balls indicate metal (M) and oxygen (X = O) atoms, respectively. (c) Contour plots of the total charge density,  $\rho_T$ . (d) Isosurfaces of difference charge density,  $\Delta\rho$ . Turquoise and yellow regions indicate depletion and accumulation of electrons, respectively. (e) Charge density isosurfaces showing p–d hybridization in the Mo–O bond. The isosurface value is taken as 0.01 electron/Å<sup>3</sup>. In the top view in panel a, unlike in graphene, M and X<sub>2</sub> occupy alternating corners of a hexagon.

structures, together with their hexagonal unit cells, contour plots of the total charge density  $\rho_T$ , and isosurfaces of difference charge density  $\Delta\rho$  (where charges of free atoms situated at the optimized crystal structure are subtracted from  $\rho_T$ ).

Based on extensive stability analysis using first-principles calculations of structure optimization, phonon frequency, formation energy, elastic properties, and finite-temperature ab initio molecular dynamics (MD) calculations, we predict that, out of 88 different MX<sub>2</sub> compounds, 52 different stable 2D single-layer H and/or T structures can occur as free-standing. Because of the instability occurring in long-wavelength acoustical modes, a few of them can be stable only at small size. Our results are summarized in Figure 3. The series of MX<sub>2</sub> compounds with M = Cr, Mo, and W and X = O, S, Se, and Te are nonmagnetic semiconductors in the H structure. On the other hand, the series with M = V, Mn, and Fe are ferromagnetic metals with a net magnetic moment (ranging from 0.2 to 3.0  $\mu_B$  per cell). Three-dimensional 2H-NbSe<sub>2</sub> has metallic and stable H structure in two dimensions, except for some instability in very-long-wavelength acoustical waves. Moreover, NbSe<sub>2</sub> also has a free-standing and stable T structure with a slightly higher energy. Interestingly, NiS<sub>2</sub> and NiSe<sub>2</sub> are metallic in the H structure, but become semiconductor in the T structure. Whereas some of these single-layer compounds in Figure 3 appear to survive up to high

**Figure 2.** Atomic structure and charge density analysis of 2D single-layer  $\text{NiS}_2$  presented as a prototype for  $\text{MX}_2$  in the T structure. temperatures, some of them are expected to become unstable as their temperatures are raised. Transition-metal oxides such as  $\text{TiO}_2$ ,  $\text{CoO}_2$ , and  $\text{NbO}_2$  and  $\text{CoS}_2$  and  $\text{CoSe}_2$  are found to be unstable in both the H and T structures. However, these single-layer  $\text{MX}_2$  compounds could be stable if they were placed on specific substrates. All of these structures display interesting electronic, magnetic, and mechanical properties and have trends correlated with the electronegativity of constituent elements X and M.

Although it is relatively easy for 2D single-layer  $\text{MX}_2$  structures to be exfoliated from parent 3D layered 2H- $\text{MX}_2$  or 1T- $\text{MX}_2$  structures, it is not obvious whether stable single layers can form if the parent 3D crystal is not layered. Following this simple methodology, by searching only the existence of parent 3D layered 2H- $\text{MX}_2$  structure from the Landolt–Bornstein database,<sup>55</sup> Ding et al.<sup>56</sup> reported that  $\text{MoSe}_2$ ,  $\text{MoTe}_2$ ,  $\text{NbSe}_2$ ,  $\text{WS}_2$ ,  $\text{WSe}_2$ ,  $\text{TaS}_2$ , and  $\text{TaSe}_2$  can have monolayer H structures and reported their electronic properties. Nonetheless, recent experimental and theoretical studies indicating that silicene,<sup>30,57–61</sup> III–V compounds,<sup>31</sup> SiC,<sup>62</sup> and  $\text{ZnO}$ <sup>63–65</sup> 2D single layers all have honeycomb structures even though their parent 3D bulk materials are not layered provide strong reasons for pursuing our analysis to search for single-layer  $\text{MX}_2$  compounds. The intention of this work was to attract interest in the manifold of single-layer  $\text{MX}_2$  compounds by showing how they can provide a wide range of options in materials research. Accordingly, rather than providing an in-depth analysis, our discussion is focused on the broad properties and various classes of  $\text{MX}_2$  compounds showing similar trends.

## METHOD

Our stability analysis and calculation of physical properties were carried out using first-principles plane-wave calculations within density functional theory (DFT) and projector-augmented-wave (PAW) potentials.<sup>66</sup> The exchange correlation potential was represented by the local density approximation<sup>67</sup> (LDA) for both spin-polarized and spin-unpolarized cases. In addition, our results were tested using the generalized gradient approximation<sup>68</sup> with the van der Waals correction.<sup>69,70</sup> All structures were treated using periodic boundary conditions. Because the electrons of some transition-metal oxides are strongly correlated, they might not be represented properly by DFT. Thus, to correct for the deficiencies of DFT, we also carried out LDA +  $U$  calculations.<sup>71</sup> All values calculated in this article were obtained using LDA unless stated otherwise.

Supercell size, kinetic energy cutoff, and Brillouin-zone (BZ) sampling of the calculations were determined after extensive convergence analysis. A large spacing of  $\sim 15$   $\text{\AA}$  between 2D single layers of  $\text{MX}_2$  was used to prevent interlayer interactions. A plane-wave basis set with kinetic energy cutoff of 520 eV was used. In the self-consistent-field potential and total energy calculations, the BZ was sampled by special  $k$  points.<sup>72</sup> The numbers of these  $k$  points were  $(37 \times 37 \times 1)$  for the primitive  $\text{MX}_2$  unit cell and were scaled according to the size of the supercells. All atomic positions and lattice constants were optimized using the conjugate gradient method, where the total energy and atomic forces were minimized. The convergence for energy was chosen as  $10^{-6}$  eV between two consecutive steps, and the maximum Hellmann–Feynman forces acting on each atom were reduced to a value of less than 0.01 eV/ $\text{\AA}$  upon ionic relaxation. The pressure in the unit cell was kept below 1 kbar.

Bader analysis is used to calculate the charge on atoms.<sup>73</sup> Because LDA is designed to describe systems with slowly varying electron densities and can fail to model localized d orbitals, more accurate electronic structure calculations were carried out using the screened-nonlocal-exchange Heyd–Scuseria–Ernzerhof (HSE) functional of the generalized Kohn–Sham scheme<sup>74,75</sup> for specific structures. Frequency-dependent  $\text{GW}_0$  calculations<sup>76</sup> were carried out to correct the LDA band gaps. However, whereas the  $\text{GW}_0$  correction was successful in predicting 3D bulk  $\text{MoS}_2$ , it seems to have overestimated the band gap of 2D  $\text{MoS}_2$  in the H structure.<sup>42</sup> This surprising situation, which is discussed later in the text, requires further analysis. Numerical calculations were performed using VASP.<sup>77,78</sup> The phonon dispersion curves and Raman-active modes were calculated using the small-displacement method (SDM)<sup>79</sup> with VASP. For critical situations, phonon calculations based on the plane-wave self-consistent-field (PWSCF) method<sup>81</sup> were also performed to carry out the analysis of Raman- and infrared-active phonon modes and check specific results.

## STABILITY ANALYSIS

$\text{MX}_2$  compounds have diverse 3D crystal structures in different space groups, as presented in Table 1. Among these, the 2H and 1T structures are layered, and hence, like graphite, they are formed by stacking of specific layers. The structures of the remaining  $\text{MX}_2$  compounds are not layered. The focus of our study was to determine which of the  $\text{MX}_2$  compounds can form stable 2D single-layer structures. Our study considered only the structures having hexagonal lattices as shown in Figures 1 and 2. These are H structures (honeycombs) with  $D_{3h}$  point-group

**Figure 3.** Summary of the results of our stability analysis comprising 44 different  $MX_2$  compounds that can form stable, 2D single-layer H and/or T structures. Transition-metal atoms indicated by M are divided into 3d, 4d and 5d groups.  $MX_2$  compounds shaded light gray form neither stable H nor T structure. In each box, the lower-lying structure (H or T) is the ground state. The resulting structures (T or H) can be half-metallic (+), metallic (\*), or semiconducting (\*\*).

symmetry and T structures (centered honeycombs) with  $C_{3v}$  symmetry. The formation of stable, single-layer  $MX_2$  compounds on a sample specific substrate might be relatively easy, but it is beyond the scope of the present study. While this study was being performed, Ding et al.<sup>56</sup> investigated electronic and vibrational properties of single-layer  $MX_2$  ( $M = Mo, Nb, W, Ta$ ;  $X = S, Se, Te$ ) in the H structure. The only reason they considered the H structure is because these compounds form stable  $2H-MX_2$  in 3D. Instead of providing tests of whether these 2D nanostructures are stable through the full spectrum of phonons and temperature-dependent ab initio MD calculations, they calculated the phonon frequencies only at the  $\Gamma$  point to reveal the Raman-active modes. Phonon dispersion spectrum analysis is an important indication of the stability of a system because phonon modes can become imaginary at other points in the BZ, when symmetry operations throughout DFT calculations are not taken into account correctly. Computationally, systems can be forced to have positive frequencies at the  $\Gamma$  point; however, this might not mean that they are stable. In our work, we carefully took into account the symmetry of the structure and calculated the full phonon dispersion of the structures. In this respect, the work by Ding et al.<sup>56</sup> had a scope different from that of the present article, and they apparently considered a small fraction of the manifold we treat here.

**Structure Optimization.** Our analysis of stability started by calculating the total energy of  $MX_2$  compounds in the single-layer H and T structures depicted in Figures 1 and 2. Optimization was performed by minimizing the total energy and atomic forces by varying the atomic positions in the unit cell and the lattice constants. If a structure was stable, optimization usually converged to the structure. Furthermore,

we calculated the cohesive energy relative to free constituent atoms. The cohesive energy per unit cell or per  $MX_2$  unit was calculated using the expression  $E_c = E_T[M] + 2E_T[X] - E_T[MX_2]$ , in terms of the total energy of  $MX_2$ ,  $E_T[MX_2]$ , and the total energies of free M and X atoms,  $E_T[M]$  and  $E_T[X]$ , respectively. We found that the calculated cohesive energies were all positive and in the range of 10–20 eV, indicating a strong cohesion relative to free atoms of the constituents. Although a positive value of  $E_c$  alone is not sufficient to indicate whether a given  $MX_2$  structure can form, the formation energy,  $E_f$ , is usually taken to be a good criterion. The formation energies  $E_f$  which were obtained by subtracting the cohesive energies of the constituent elements in their equilibrium (bulk, liquid, or gas) phases,  $E_c[M]$  and  $E_c[X]$ . Specifically,  $E_f = E_c - E_c[M] - 2E_c[X]$ . For the sake of comparison, we calculated  $E_f$  using both experimental cohesive energies<sup>80</sup> and calculated cohesive energies of the constituent elements. Calculated formation energies were positive for all H and T structures that were found to be stable as a result of a series of stability analyses.

The optimized lattice constants and other structure parameters of stable structures are also presented in Table 1. Experimental data on the lattice constants of  $MX_2$  compounds in the H structure are not available yet. Even though the lattice constants of  $MoS_2$  in the H structure (which is the most studied single-layer  $MX_2$ ) have not been measured experimentally yet, they can be inferred from the lattice constants of  $2H-MoS_2$ . Thus, the lattice constants of  $MoS_2$  are expected to be close to those of  $2H-MoS_2$ , which were measured to be  $a = b = 3.16$  Å. The LDA is known to predict overbinding and, hence, lattice constants that are slightly shorter than the experimental

<sup>a</sup>Values in parentheses were calculated using experimental cohesive energies of constituent elements. <sup>b</sup>Only for selected compounds. <sup>c</sup>Positive sign indicates depletion of electrons. <sup>d</sup>Negative sign indicates excess electrons. <sup>e</sup>Structures having indirect band gap according to LDA (and GW<sub>0</sub>) calculations are indicated with bold face. <sup>f</sup>Abbreviations used for 3D bulk structures: 4H = 4H-MX<sub>2</sub>, 2H = 2H-MX<sub>2</sub>, 3R = 3R-MX<sub>2</sub>, 1T = 1T-MX<sub>2</sub> structure; R = rutile, P = pyrite, M = molecule, Mcl = monoclinic, Ma = marcasite crystal structure. <sup>g</sup>All values in this table were calculated using LDA, as detailed in the Method section. <sup>h</sup>Metastable crystal, \*; distorted lattice structure, +.

values. In our study, the LDA and GGA + vdW predictions were 3.11 and 3.22 Å, respectively.

In closing this section, we point out that the energetics discussed here, namely, the cohesive energies or formation energies of the MX<sub>2</sub> single-layer H and T structures, do not change significantly in their layered 3D crystals. Even if some dimensionality effects can be observed,<sup>46,47</sup> the interactions between adjacent layers are usually weak and on the order of 100–200 meV. Earlier studies showed<sup>41–43</sup> that the interlayer interactions originate mainly from van der Waals attractions, and hence, stacking or surface energy of 3D MX<sub>2</sub> crystals is expected to be small and in the range of ~100 meV.

**Lattice Dynamics.** Even if the total energy of a structure can be minimized, its stability cannot be assured. Therefore, frequencies of the vibration modes of optimized single-layer MX<sub>2</sub> in the H or T structure were calculated for all *k* points in the BZ to provide a rigorous test for the stability of a given structure. A structure is taken to be stable only when calculated frequencies of all phonon modes in the BZ are positive; otherwise, imaginary frequencies indicate instability. In such calculations, the long-wavelength, out-of-plane acoustical (ZA) modes are vulnerable to instability. Thus, caution has to be taken in calculating forces with extreme accuracy.<sup>121</sup>

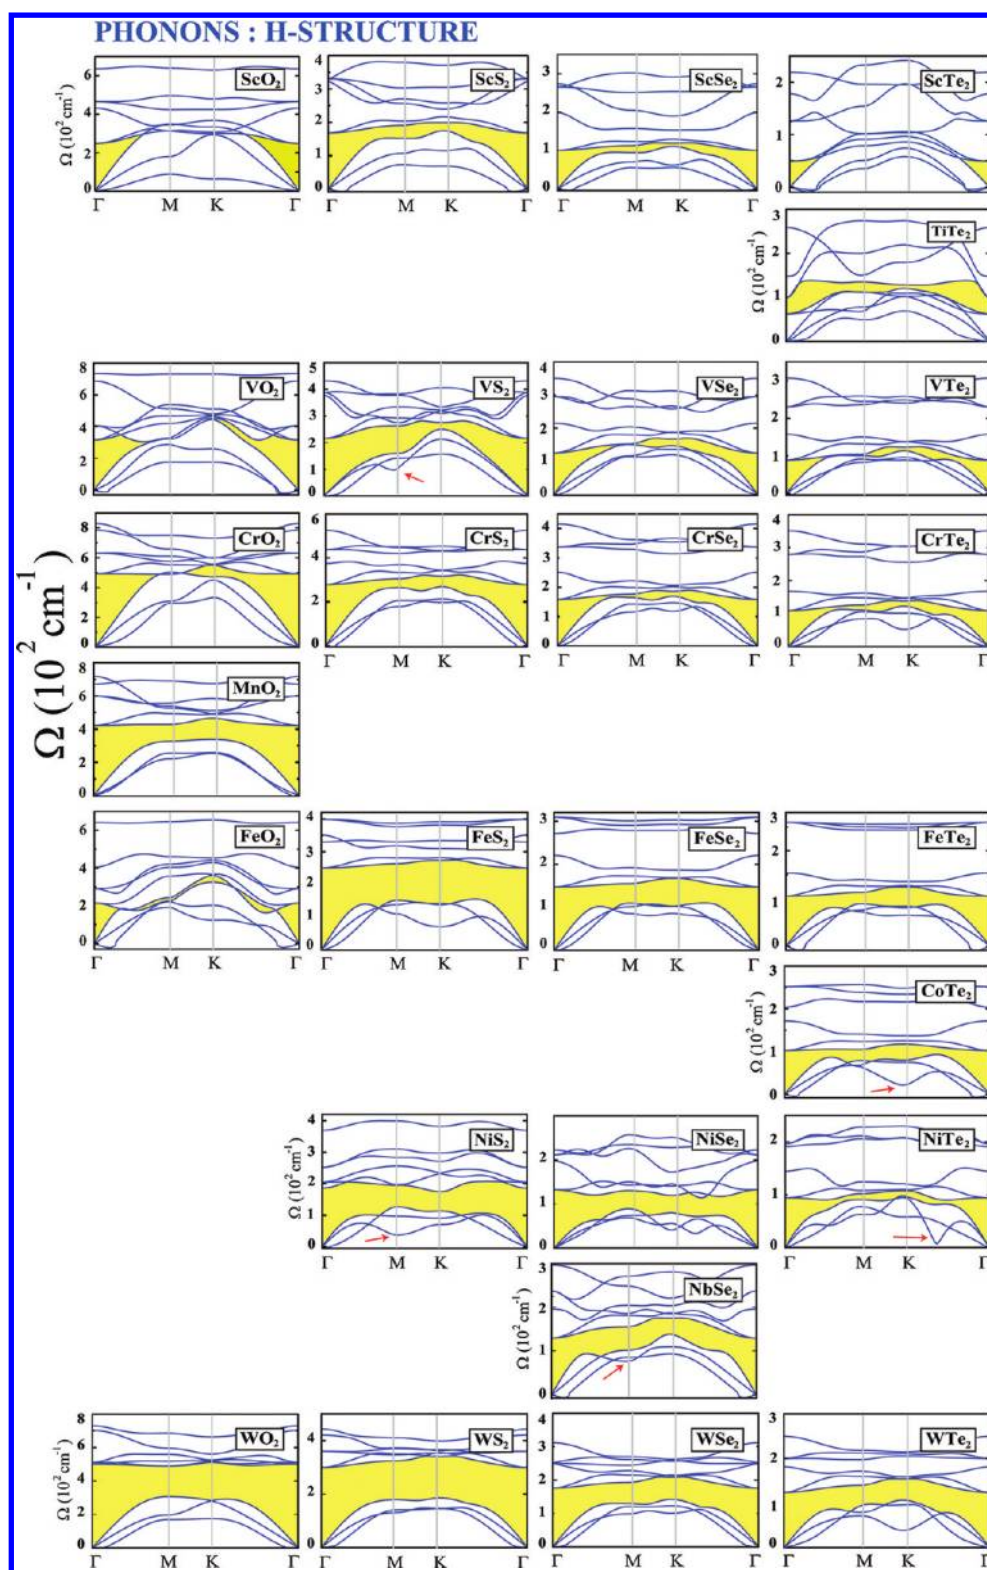

In Figures 4 and 5, we present the calculated phonon branches of MX<sub>2</sub> compounds in the H and T structures, respectively, which display three acoustical branches separated by a gap from six optical branches. All 52 2D single-layer MX<sub>2</sub> compounds presented in Figures 4 and 5 have positive frequencies in the BZ, except for a few of them that have imaginary frequencies in a small region of Ω(*k*) → 0 (or λ → ∞). Calculations of frequencies in this region of the BZ require very high accuracy for the calculation of forces. Therefore, the structural instability as λ → ∞ might arise due to numerical calculations. Even if the instability of MX<sub>2</sub> compounds as λ → ∞ were a reality, the compounds could be stabilized at small sizes. Moreover, because of limitations of DFT for highly correlated electron systems, some MO<sub>2</sub> compounds having H and T structures can have imaginary frequencies at the center of the BZ. Nonetheless, in the following sections, we further explore the possible instabilities of specific compounds using finite-temperature ab initio MD and LDA + *U* calculations.

The phonon frequencies of the series of MoX<sub>2</sub> (X = O, S, Se, and Te) are plotted on the same scale of frequency in Figure 6 for the sake of detailed discussion of the trends related to

chalcogen atoms. As the row number of X decreases, the X atoms become lighter, and the M–X bonds become more ionic. Consequently, the width of the acoustical branches increase from Ω = 119 cm<sup>−1</sup> to Ω = 405 cm<sup>−1</sup>, and the highest frequency of the optical modes also increases as X goes from Te to O. As an example, whereas the highest frequency of the transverse optical (TO) mode of MoTe<sub>2</sub> at the Γ point is Ω = 298 cm<sup>−1</sup>, the frequency of the same mode of MoO<sub>2</sub> occurs at Ω = 733 cm<sup>−1</sup>. Among stable single-layer MX<sub>2</sub> compounds, CrO<sub>2</sub> has the highest TO frequency, Ω(*k* = 0) = 824 cm<sup>−1</sup>. That the width of the phonon branches increases with decreasing row number of X atoms generally occurs for other M atoms in both the H and T structures. Longitudinal acoustic (LA) branches have linear dispersions as *k* → 0, whereas ZA (out-of-plane) modes display parabolic dispersion owing to the rapid decay of transverse force constants.

Owing to the limited experimental data on the phonon spectrum, we checked our results regarding the lattice dynamics of stable H and T structures of MX<sub>2</sub> crystals with the available Raman (R) and infrared (IR) data. Because experimental data are available only for single-layer MoS<sub>2</sub> and WS<sub>2</sub>, one can compare the frequencies of Raman-active modes calculated for these single-layer compounds. The calculated frequencies of the Raman-active modes, namely, E' = 380 cm<sup>−1</sup> and A' = 406 cm<sup>−1</sup>, are in agreement with the corresponding experimental data,<sup>46</sup> E' = 384 cm<sup>−1</sup> and A' = 403 cm<sup>−1</sup>. Similarly, the LDA-calculated frequencies of Raman-active modes of WS<sub>2</sub>, E' = 359 cm<sup>−1</sup> and A' = 412, are in fair agreement with the experimental data,<sup>47</sup> E' = 350 cm<sup>−1</sup> and A' = 415 cm<sup>−1</sup>. Also, experimentally, the IR-active modes at the center of the BZ are observed as 384 and 470 cm<sup>−1</sup>, which were predicted in the present study using LDA as 359 and 437 cm<sup>−1</sup>, respectively. Moreover, the Raman-active modes calculated by LDA are able to reproduce the anomalous dimensionality effect between 3D 2H-MoS<sub>2</sub> and 2D MoS<sub>2</sub> in the H structure as revealed by Lee et al.,<sup>46</sup> namely, that whereas the A' mode softens, E' becomes stiffer upon going from 2D to 3D.

Significant charge transfer and resulting polar character is the marked feature of 2D MX<sub>2</sub> compounds. Unlike graphene and silicene,<sup>30,57–61,122,123</sup> the H and T structures of MX<sub>2</sub> exhibit an interesting charge distribution, as shown in Figures 1 and 2, specifically, the outer planes of X atoms are negatively charged, whereas the plane of M atoms between them is positively charged. Bader analysis<sup>73</sup> indicates that electrons from M atoms

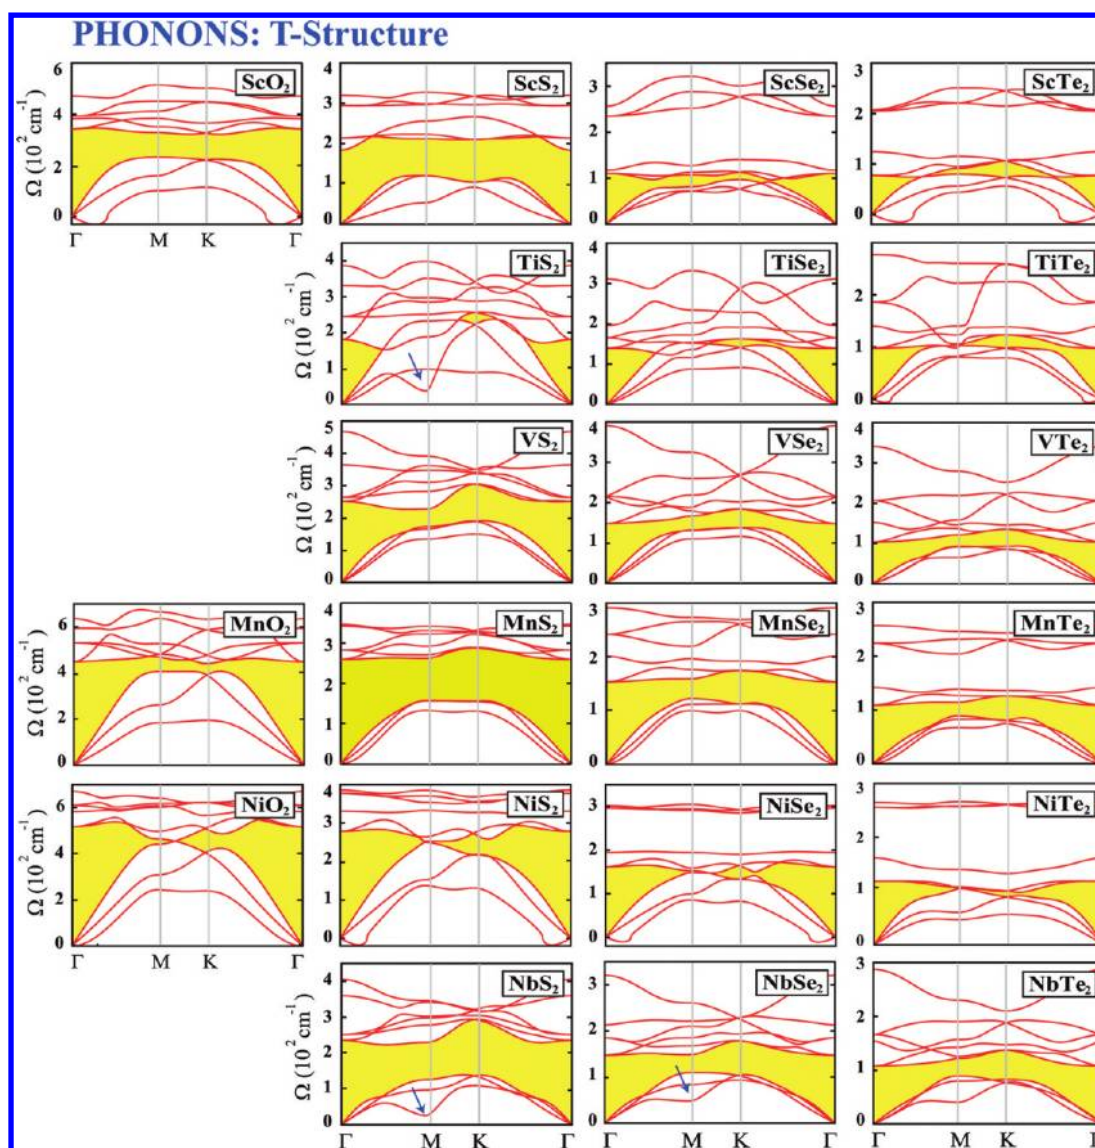

**Figure 4.** Calculated phonon branches of 2D single-layer  $\text{MX}_2$  compounds that are stable in the H structure. Phonon dispersions are presented along the  $\Gamma$ –M–K– $\Gamma$  directions of the BZ. The gaps between acoustical and optical branches are shaded. The transverse acoustical ZA branch has parabolic dispersion as  $k \rightarrow 0$ . Different scales of frequency are used for different materials. The phonon dispersion curves of  $\text{MoX}_2$  ( $X = \text{O}, \text{S}, \text{Se}$ , and  $\text{Te}$ ) are presented in the same scale of frequency in Figure 6. Dips that can be associated with Kohn anomalies are indicated by arrows.

are transferred to two X atoms, leaving a depletion of electronic charge on M (i.e.,  $\rho_{\text{M}} > 0$ ) and an excess of electronic charge on X (i.e.,  $\rho_{\text{X}} < 0$ ). As expected,  $\rho_{\text{M}} = 2|\rho_{\text{X}}|$ . However,  $\text{CoTe}_2$  and  $\text{NiTe}_2$  appear to be exceptions, where the direction of charge

transfer is reversed according to Bader analysis. Also, excluding a few exceptions in transition-metal oxides,  $\rho_{\text{M}}$  increases with decreasing row number of the X atom. The Born effective charges, which can be obtained from the treatment of lattice

**Figure 5.** Calculated phonon branches of 2D single-layer MX<sub>2</sub> compounds that are stable in the T structure. Phonon dispersions are presented along the  $\Gamma$ –M–K– $\Gamma$  directions of the BZ. The gaps between acoustical and optical branches are shaded. The transverse acoustical ZA branch has parabolic dispersion as  $k \rightarrow 0$ . Different scales of frequency are used for different materials. Dips that can be associated with Kohn anomalies are indicated by arrows.

dynamics, are in compliance with the direction of charge transfer revealed through the Bader analysis of MoS<sub>2</sub>. For example, the Born effective charges calculated for MoS<sub>2</sub> are  $Z_{\text{Mo}}^{\parallel} = 1.211$ ,  $Z_{\text{Mo}}^{\perp} = 0.075$  electron and  $Z_{\text{S}}^{\parallel} = -0.573$ ,  $Z_{\text{S}}^{\perp} = -0.043$  electron.

The phonon dispersion curves of specific compounds, such as VS<sub>2</sub>, CoTe<sub>2</sub>, NiS<sub>2</sub>, NiTe<sub>2</sub>, and NbSe<sub>2</sub> in the H structure and TiS<sub>2</sub>, NbS<sub>2</sub>, and NbSe<sub>2</sub> in the T structure, exhibit dips or local minima in the BZ, as seen in Figures 4 and 5. Even more remarkable is that an acoustical branch of NiTe<sub>2</sub> dips until its frequency becomes zero for  $k$  between K and  $\Gamma$  points. These structures in the phonon bands lead to discontinuities in  $\partial\Omega/\partial k$  and are associated with Kohn anomalies.<sup>124</sup> They occur at specific  $k$  vectors in the BZ, where the dielectric constant  $\epsilon(k)$  goes through a singularity, causing an abrupt change in the electron screening of the lattice potential. This singularity, in turn, is reflected in the phonon dispersion curves. NiTe<sub>2</sub> is an extreme case, which can happen in low-dimensional materials and indicates a static distortion of the crystal.

**Ab Initio Molecular Dynamics Calculations.** If the analysis based on phonon calculations indicates the stability of an MX<sub>2</sub> compound under study at  $T = 0$  K, this stability could be destroyed at elevated temperatures. In certain cases, the stable structure might correspond to a shallow minimum in the Born–Oppenheimer surface, in which case the instability occurs already at low temperatures. Additionally, in certain structures, imaginary frequencies for phonon modes can occur near the center of the BZ. Thus, one has to clarify whether imaginary frequencies occurring for  $\lambda \rightarrow \infty$  can cause an instability or whether they are only an artifact of numerical calculations. If a structure is unstable at  $T = 0$  K, it is distorted or disintegrated when atoms are displaced from their equilibrium positions in the course of a large number of time steps between two velocity normalizations. Thus, the possibilities that a compound can be unstable were further tested for specific compounds using first-principles molecular dynamics (MD) calculations at temperatures of  $T = 500$ , 1000, and 1500 K. The time steps were taken to be  $2 \times 10^{-15}$  s, and

**Figure 6.** Calculated phonon branches of stable H structures of  $\text{MoX}_2$  ( $X = \text{O}, \text{S}, \text{Se}, \text{and Te}$ ) compounds along the  $\Gamma$ – $M$ – $K$ – $\Gamma$  directions of the BZ. Phonon branches are labeled by numerals. The acoustical and optical phonon modes at the  $\Gamma$  point are depicted in the bottom panel. All branches are presented using the same scale of frequency.

the velocities of the atoms were normalized every 40 steps for  $T = 500$  K and every 100 steps for  $T = 1000$  and  $1500$  K.

For the H structure, we considered  $\text{FeTe}_2$ ,  $\text{MoO}_2$ ,  $\text{VO}_2$ , and  $\text{VSe}_2$ . The first three compounds have 3D crystals that are different from layered 2H and 1T structures, and hence, it seems unlikely that these three compounds can occur in stable H structures. In addition, because of the imaginary frequencies as  $\Omega(\mathbf{k}) \rightarrow 0$  in a small region,  $\text{FeTe}_2$  and  $\text{VO}_2$  are vulnerable to instability as  $\lambda \rightarrow \infty$ .  $\text{VSe}_2$  has a layered 1T structure, and hence, one needs to confirm whether the H structure can really occur even if it is less energetic than the T structure. To avoid the stability, which can be imposed by periodic boundary conditions using a  $(1 \times 1)$  unit cell, calculations were carried out using  $(4 \times 4)$  supercells. All four compounds remained intact after many steps (300 time steps) at  $T = 500$  K. If they were unstable already at  $T = 0$  K, their structure would be dissociated at this temperature even before 300 time steps. Then, calculations were switched to  $T = 1000$  K starting from atomic velocities of the final step at  $T = 500$  K. Higher temperatures and normalization at relatively larger numbers of steps can speed the onset of the instability, which would normally occur at relatively lower temperatures after a large number of steps. If the system continues to remain stable after a sufficiently large number of steps at  $T = 1000$  K, we raised the temperature and let the MD calculations run at  $T = 1500$  K. The temperature  $T = 1500$  K is rather high and is expected to accelerate the occurrence of a structural instability, which could have occurred at relatively low temperatures. In fact, whereas the H structure of  $\text{FeTe}_2$  remained stable after 304 steps at  $T = 1000$  K, it severely distorted after 562 steps at  $T = 1500$  K.  $\text{MoO}_2$  in the H structure was stable after 546 steps at  $T = 1000$  K and remained stable after 760 steps at  $T = 1500$  K. We concluded that  $\text{MoO}_2$  can remain stable in the H structure at moderate temperatures. The situation with  $\text{VO}_2$  is similar to that of  $\text{MoO}_2$ , except that an O atom desorbed after 530 time steps at  $T = 1500$  K.  $\text{VSe}_2$  continued to be stable after 1429 time steps at  $T = 1500$  K. The final geometries of  $\text{MX}_2$  structures after several time steps are shown in Figure 7.

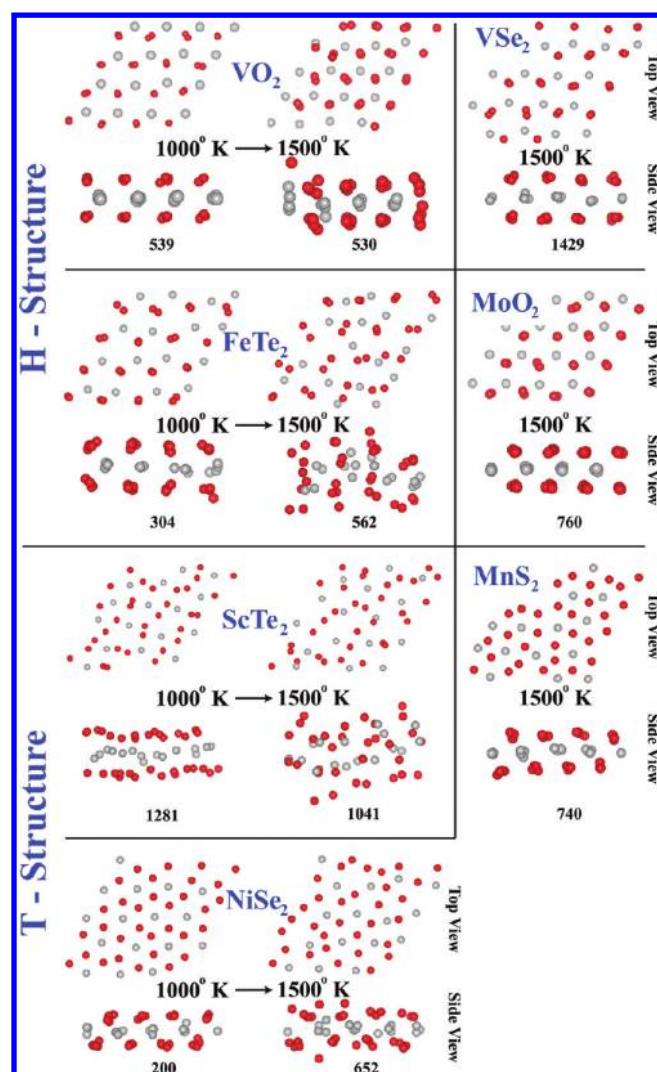

For the T structure, we considered  $\text{MnS}_2$ ,  $\text{ScTe}_2$ , and  $\text{NiSe}_2$ , because their specific acoustical modes have imaginary

frequencies near the center of the BZ. Ab initio MD calculations showed that  $\text{MnS}_2$  was stable after 740 steps at  $T = 1000$  K and continued to be stable after 700 steps at  $T = 1500$  K with almost-perfect centered honeycombs. However, the situation was different for  $\text{ScTe}_2$  and  $\text{NiSe}_2$ .  $\text{ScTe}_2$  became distorted already after 1281 time steps at  $T = 1000$  K and became severely distorted and dissociated after 1041 time steps at  $T = 1500$  K. The centered honeycomb structure of  $\text{NiSe}_2$ , which was maintained after 200 steps at  $T = 1000$  K, was severely distorted after 652 time steps at  $T = 1500$  K. These results of MD calculations imply that imaginary frequencies near the center of the BZ revealed from the phonon calculations of  $\text{ScTe}_2$  and  $\text{NiSe}_2$  having T structures are not artifacts of numerical accuracy.

In concluding this section, the present analysis shows that single-layer  $\text{MX}_2$  compounds having positive frequencies at all  $\mathbf{k}$  points in the BZ are stable at 0 K; most of them continue to be stable above room temperature, once they are synthesized or produced in the H or T structures. On the other hand, specific compounds for which imaginary frequencies are calculated near the center of the BZ can be vulnerable to structural instability, if these frequencies are not artifacts of numerical accuracy and these compounds are not stabilized because of their small size. Similarly, relatively small formation energies  $E_f$  and/or small in-plane stiffness values  $C$  (presented in Table 1) calculated for any single-layer  $\text{MX}_2$  compound can also imply the instability. Under these circumstances, ab initio MD calculations present evidence that a compound is unstable and ready for dissociation. In this respect, among compounds that needed further tests through ab initio MD calculations, the stabilities of  $\text{FeTe}_2$  and  $\text{VO}_2$  in the H structure and  $\text{ScTe}_2$  and  $\text{NiSe}_2$  in the T structure were found to be weak.

**Mechanical Properties.** The strength of nanostructures is crucial for their use in diverse nanotechnology applications. Elastic constants can provide further indications about the strength of stable H and T structures. A honeycomb structure usually underlies the unusual mechanical properties providing high in-plane strength and flexibility in deformations perpendicular to the atomic planes. We focused on the harmonic range of the elastic deformation, where the structure

**Figure 7.** Top and side views of snapshots corresponding to atomic structures of selected  $\text{MX}_2$  compounds taken from ab initio molecular dynamic (MD) calculations at specified temperatures and time steps indicated by numerals below each panel. MD results at  $T = 1000$  K are also shown for structures that become unstable at  $T = 1500$  K.

responded to strain  $\varepsilon$  linearly and reversibly. Here,  $\varepsilon$  is the elongation per unit length. The strain energy is defined as  $E_s = E_T(\varepsilon) - E_T(\varepsilon = 0)$ , that is, the total energy at a given strain minus the total energy at zero strain. Normally, the Young's modulus characterizes the mechanical strength of bulk materials. However, the definition of the width of an H or T structure is not unambiguous, and hence, instead of the Young's modulus of a single-layer  $\text{MX}_2$  structure, one can use the in-plane stiffness  $C = (1/A_0)(\partial^2 E_s / \partial \varepsilon^2)$ , in terms of the uniform stress and equilibrium area of the supercell,  $A_0$ .<sup>31</sup> The calculated in-plane stiffness values of single-layer  $\text{MX}_2$  materials presented in Table 1, ranging from 250 to 9 N/m, can be contrasted with the values calculated for graphene and BN, 357 N/m (experimental value  $340 \pm 50$  N/m) and 267 N/m, respectively. We note that, generally, in-plane stiffness values increase with decreasing row number of X; stated differently, an  $\text{MX}_2$  compound softens as the row number of X increases. Thus, the calculated values of  $C$  are usually low for compounds having  $X = \text{Te}$ . This trend is in compliance with the trend outlined in Figure 6. The in-plane stiffness of  $\text{WX}_2$  is usually

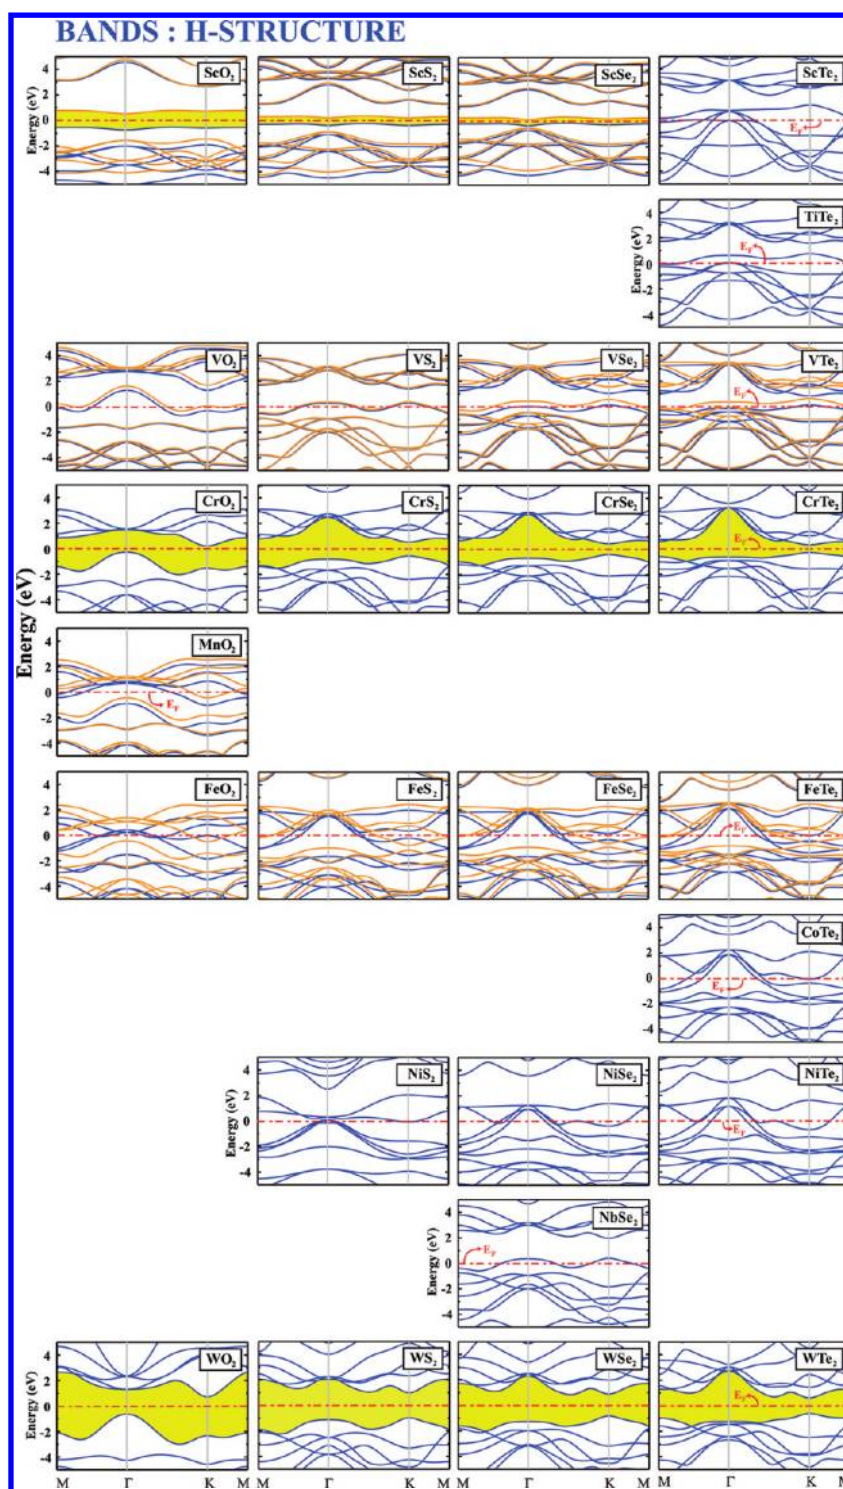

higher than those of other  $\text{MX}_2$  compounds. Also, the  $C$  value of the H structure is usually higher than that of the T structure if both structures occur for the same compound. Finally,  $\text{MX}_2$  compounds having  $C$  values that are marked by boldface in Table 1 do not deform symmetrically. A low value of  $C$  and nonuniform deformation under uniform stress imply possible instability at finite temperatures.

## ELECTRONIC AND MAGNETIC PROPERTIES

The stable  $\text{MX}_2$  compounds in the H and T structures display a rich diversity of electronic and magnetic properties. Depending on the combination of M and X, single-layer  $\text{MX}_2$  compounds can be semiconductor, ferromagnetic, or nonmagnetic metals. In Figures 8–10 we present the electronic energy band structures of all stable  $\text{MX}_2$  compounds having H and T structures. Because of the available experimental data, the band structure of the manifold  $\text{MoX}_2$  ( $X = \text{O}, \text{S}, \text{Se}, \text{Te}$ ) in the H structure is given separately in Figure 10 for detailed discussion. The  $\text{MS}_2$  manifold ( $M = \text{Sc}, \text{V}, \text{Cr}, \text{Fe}, \text{Ni}$ , and  $\text{W}$ ) includes semiconductors and magnetic and nonmagnetic metals in both the H and T structures.

Semiconducting single-layer  $\text{MX}_2$  compounds having the H structure can be treated in two groups that display rather different band structures. The first group, transition-metal oxides (i.e.,  $M = \text{Sc}, \text{Cr}, \text{Mo}, \text{W}$ ;  $X = \text{O}$ ) differ from the other group (i.e.,  $M = \text{Cr}, \text{Mo}, \text{W}$ ;  $X = \text{S}, \text{Se}, \text{Te}$ ) by their relatively smaller band gaps and lower band-edge state densities. Here, we discuss these groups by considering the band structures of  $\text{MoO}_2$  and  $\text{MoS}_2$  as prototypes, as shown in Figure 10. For both groups, the bands at the edges of the conduction and valence bands are composed from Mo 4d and X p orbitals. However, the types (symmetries) and contributions of these orbitals vary with  $k$  and with the constituents M and X. The M–X bonds of single-layer  $\text{MoO}_2$  are 0.3–0.7 Å shorter than those of the second group. As a result, the highest valence band at  $\Gamma$ , which is combined from Mo  $d_{z^2}$  and O  $p_z$  orbitals has higher dispersion. This band is pushed up toward the conduction band to lower the indirect band gap between the conduction-band minimum at the K point and the valence-band maximum at the  $\Gamma$  point. Accordingly, the smallest band gaps of all  $\text{MO}_2$  honeycomb structures including  $\text{MoO}_2$  are indirect. On the other hand, the topmost valence band of  $\text{MoS}_2$ , which has a relatively higher Mo  $d_{z^2}$  contribution and relatively longer M–X bonds, is flattened, and its energy is lowered. Under these circumstances, the smallest band gap of the second group is usually direct (except for  $\text{MoSe}_2$ , which has an indirect gap only 4 meV smaller than the direct one) and occurs at the K point between the conduction-band minimum (80% Mo d and 20% S  $p_x$ ) and the valence-band maximum (90% Mo  $d_{x^2-y^2}$  and 10% S  $p_x$ ). The characters of these states at the K point are similar for  $X = \text{S}, \text{Se}$ , and  $\text{Te}$ , but their direct band gap decreases slightly on going from S to Te, because the lattice constants,  $a = b$ , increase from 3.12 to 3.46 Å. The isosurface charge densities of states at the band edges of  $\text{MoSe}_2$  and  $\text{MoTe}_2$  are also presented. The direct band gap of  $\text{MoO}_2$  at the K point is significantly larger than that of  $\text{MoS}_2$ , because the Mo–O bond is much shorter (2.78 Å). The distinction between the energy band structures of the first group and the second group is also seen in the calculated total and orbital densities of states given in Figure 10. Another noteworthy trend that we deduced from our calculations is that, for all single-layer  $\text{MX}_2$  semiconductors, the band gap generally increases as M goes from Sc to W. Despite the striking similarity of the band structures of  $\text{MX}_2$

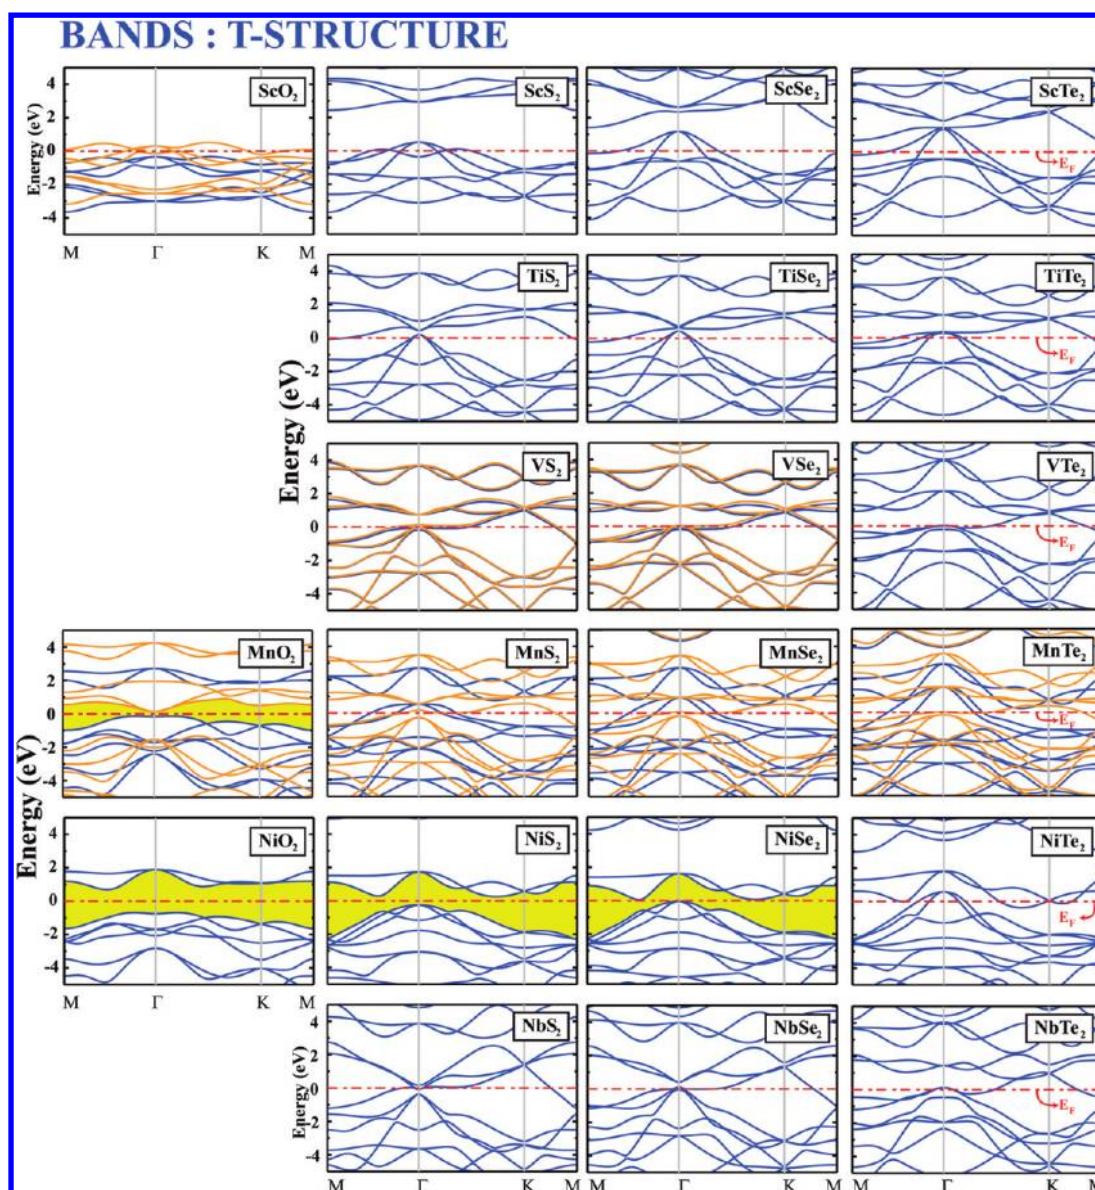

**Figure 8.** Calculated electronic band structures of 2D stable  $\text{MX}_2$  compounds that are stable in the H structure. The zero of the energy is set to the Fermi level,  $E_F$ , shown by red dash-dotted lines. The energy gaps of semiconductors are shaded (yellow). For nonmagnetic states, spin-degenerate bands are shown as blue lines. For magnetic structures, blue lines represent spin-up bands, whereas orange lines are spin-down states. In the same row, stable structures with the same M atom but different X atoms are presented. Columns present the  $\text{MX}_2$  manifold with the same X atom but differing M atoms. The manifold  $\text{MoX}_2$  ( $X = \text{O}, \text{S}, \text{Se}, \text{Te}$ ) in the H structure is presented separately in Figure 10.

( $X = \text{O}, \text{S}, \text{Se}, \text{and Te}$ ) as M goes from V to W, they are essentially either metal or semiconductor depending on the number of s and d valence states of the free M atoms.

We note that ferromagnetic metals, such as  $\text{VX}_2$  or  $\text{FeX}_2$  ( $X = \text{O}, \text{S}, \text{Se}, \text{Te}$ ), in the H structure have magnetic moments that are located at the d orbitals of the transition-metal atoms.

However, in the case of  $\text{ScX}_2$  ( $X = \text{O}, \text{S}, \text{Se}$ ), the magnetic moment is located at the site of the chalcogen atoms because of the crucial amount of transfer of charge from Sc to X, since Sc atom have relatively low electronegativity with respect to that of chalcogen atoms. In all magnetic structures, we further carried out supercell calculations to take into account the

**Figure 9.** Calculated electronic band structures of 2D stable  $\text{MX}_2$  compounds that are stable in the T structure. The zero of the energy is set to the Fermi level,  $E_F$ , shown by red dash-dotted lines. The energy gaps of semiconductors are shaded (yellow). For nonmagnetic states, spin-degenerate bands are shown as blue lines. For magnetic structures, blue lines represent spin-up bands, whereas orange lines are spin-down states. The manifold  $\text{MX}_2$  with the same M atom but different X atoms is presented in the same row. Columns present  $\text{MX}_2$  manifolds with the same X atom but differing M atoms.

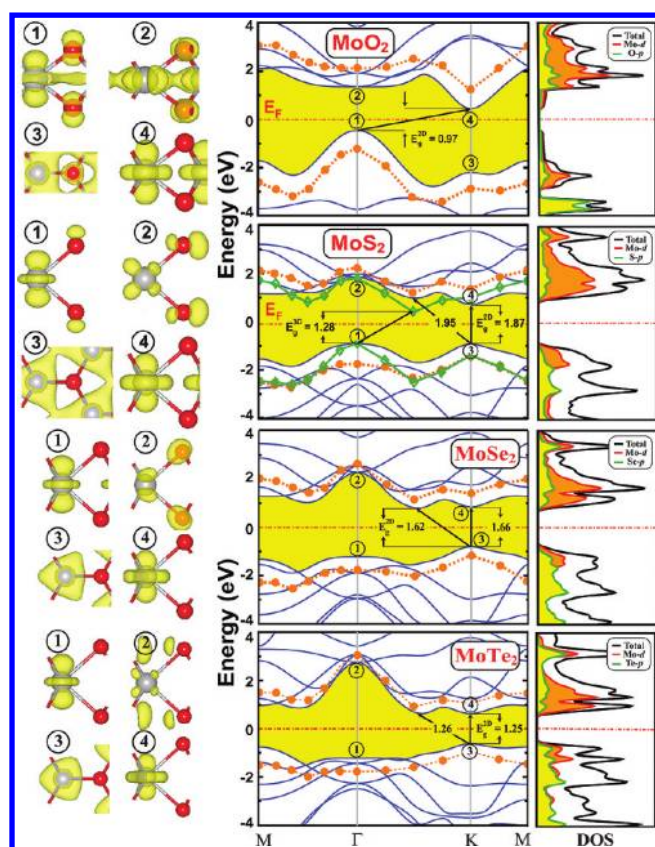

antiferromagnetic ordering in neighboring unit cells. We conclude that ferromagnetic ordering is the energetically most favorable arrangement. We also addressed the question of whether the metallicity of  $\text{MO}_2$  compounds, namely,  $\text{VO}_2$ ,  $\text{MnO}_2$ , and  $\text{FeO}_2$ , in the H structure and  $\text{ScO}_2$  in the T structure, is an artifact of LDA. Normally, these oxides are expected to be wide band gap semiconductor. To this end, we carried out electronic energy structure calculations using HSE06<sup>74,75</sup> functionals, which confirmed our LDA results.

Because DFT usually underestimates band gaps, we first compared the band gap calculated for 3D layered 2H-MoS<sub>2</sub> with the corresponding experimental values. The present study estimates the indirect band gap of 2H-MoS<sub>2</sub> as 0.72 eV, which is 0.51 eV smaller than the experimental value of  $E_g = 1.23$  eV.<sup>125</sup> It is well-known that the bulk band gaps of Si and Ge are also underestimated by LDA. Under these circumstances, the

band gaps of 3D 2H-MoS<sub>2</sub> and 2D MoX<sub>2</sub> manifold in the H structures were corrected by carrying out frequency-dependent  $\text{GW}_0$  calculations.<sup>76</sup> In these calculations, the screened Coulomb potential,  $W$ , is kept fixed to the initial DFT value  $W_0$ , and the Green's function,  $G$ , is iterated several times. Various tests regarding vacuum separation; kinetic energy cutoff; and numbers of bands,  $k$  points, and grid points were made. Final results of for the  $\text{GW}_0$  corrections were obtained using  $(12 \times 12 \times 1)$   $k$  points in the BZ, a 400-eV cutoff potential, 192 bands for single-layer structures (384 for 3D 2H-MoS<sub>2</sub>), and 64 grid points. The  $\text{GW}_0$ -corrected band gap of 2H-MoS<sub>2</sub> was found to be 1.28 eV, which is in good agreement with experimental value of 1.23 eV.<sup>125</sup>

The band gap of single-layer 1H-MoS<sub>2</sub> was calculated as 1.87 eV with LDA, whereas a recent experimental study<sup>34</sup> using complementary techniques of optical absorption, photoluminescence,

**Figure 10.** Calculated energy band structures, charge densities, and state densities of single-layer  $\text{MoX}_2$  ( $X = \text{O}, \text{S}, \text{Se}, \text{and Te}$ ). Left panels are isosurface charge densities of the specific states at the band edges indicated by numerals. The isosurface value is taken as  $0.01 \text{ electron}/\text{\AA}^3$ . Middle panels are band structures along the  $M-\Gamma-K-M$  directions of the Brillouin zone. The LDA band gap between the conduction and valence bands is shaded. The zero of energy is set at the Fermi level,  $E_F$ , shown by red dash-dotted line. The  $\text{GW}_0$ -corrected bands are indicated by orange dashed lines and dots. The  $\text{GW}_0$ -corrected band gap of 3D 2H- $\text{MoS}_2$  is indicated by green lines and diamonds. Direct and indirect band gap values are given in units of eV. Right panels are total and orbital-projected densities of states.

and photoconductivity reported its value as 1.90 eV. The band gap increased by  $\sim 0.70 \text{ eV}$  and changed from indirect to direct upon going from a 3D layered structure to the single-layer H structure. Three-dimensional 2H- $\text{MoS}_2$  consists of 1H- $\text{MoS}_2$  layers attracted by a weak van der Waals interaction of 96 meV per layer.<sup>43</sup> The chemical interaction is negligible (only 7 meV), and the interlayer spacing is large  $\sim 6.1 \text{ \AA}$ . Under these circumstances, it is remarkable that confinement effects can give rise to such a change in the band gap.<sup>34</sup> In Figure 10, the change from an indirect to a direct gap by lowering the dimensionality from 3D to 2D is shown. This transition of indirect to direct gap is expected to occur gradually as the number of layers in  $\text{MoS}_2$  sheets decreases and could have important implications.<sup>34,40</sup>

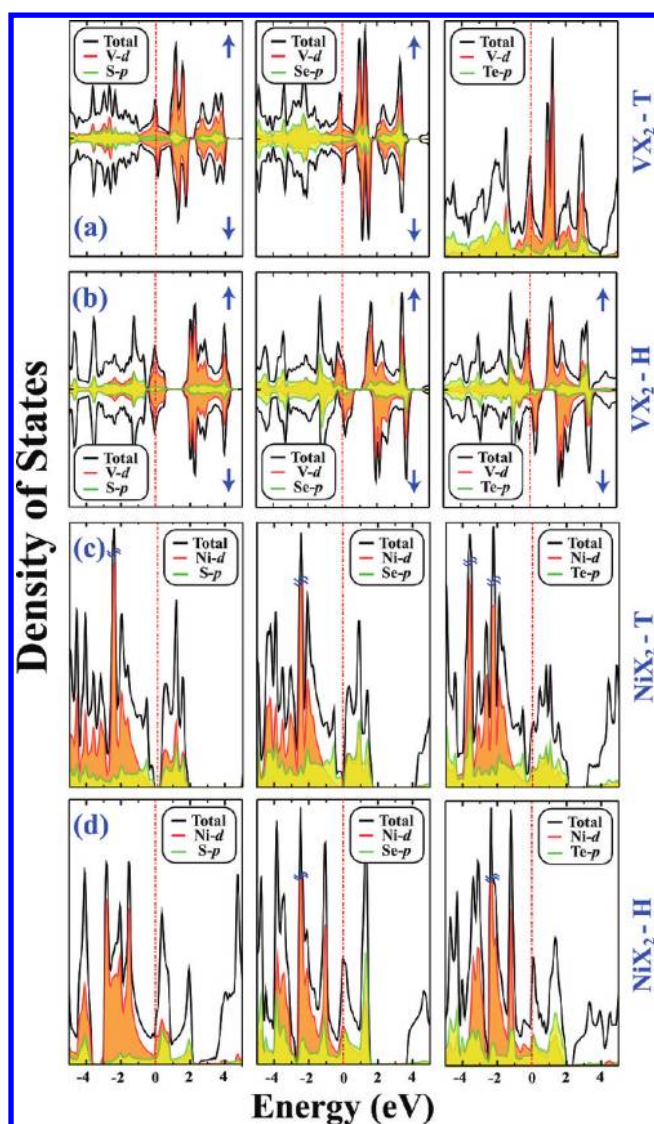

Here, we address a crucial issue that the LDA result for 2D 1H- $\text{MoS}_2$  is so close to the experimental value, whereas it underestimates the 3D bulk value by 0.51 eV. On the other hand, the situation that the band gap of 2H- $\text{MoS}_2$  (which is underestimated by LDA as 0.72 eV) is successfully corrected by  $\text{GW}_0$  as 1.28 eV, whereas the band gap of single-layer 1H- $\text{MoS}_2$  (which is predicted successfully by LDA as 1.87 eV) is overestimated upon  $\text{GW}_0$  correction as 2.57 eV is rather

paradoxical. Incidentally, similar situations also occur for other single-layer honeycomb structures. For example,  $\text{GW}_0$  corrections result in surprisingly large band gap values for single-layer BN and CF (fully fluorinated graphene) and graphane CH having honeycomb structures.<sup>126</sup> (The LDA band gap of fully fluorinated graphene CF is 2.98 eV, the LDA +  $\text{GW}_0$  corrected band gap is 7.49 eV, and the experimental band gap is 3.0 eV.<sup>127</sup> Also, for graphane CH, the LDA band gap is 3.42 eV, and the LDA +  $\text{GW}_0$  correction is 5.97 eV.<sup>128</sup>) Not only LDA +  $\text{GW}_0$  but also the screened-nonlocal-exchange HSE<sup>74</sup> functional recommended for localized d bands yielded band gap of  $\text{MoS}_2$  significantly larger than 1.90 eV with/without the  $\text{GW}_0$ <sup>42,75</sup> correction. These results suggest that the overestimation of the band gap of some single-layer structures by the  $\text{GW}_0$  correction might originate from the fact that LDA alone already provides a good estimate of the band gap of 1H- $\text{MoS}_2$ . It is expected that the same situation might be valid for other  $\text{MX}_2$  semiconductors and that their band gaps can be overestimated by the  $\text{GW}_0$  correction. Unfortunately, we cannot further explore the capacity of the  $\text{GW}_0$  correction for other single-layer H and T structures, because no experimental data exist for comparison. Nevertheless, this paradoxical situation will be resolved when additional experimental data on the band gaps of single-layer  $\text{MX}_2$  structures become available. It is also emphasized that, whereas  $\text{MO}_2$  compounds (for  $M = \text{Cr}, \text{Mo}, \text{and W}$ , which occupy the same column in the Periodic Table) are indirect-band-gap semiconductors, other  $\text{MX}_2$  compounds with  $M = \text{Cr}, \text{Mo}, \text{and W}$  and  $X = \text{S}, \text{Se}, \text{and Te}$  are direct-band-gap semiconductors.

The bands of  $\text{MX}_2$  in the T structure are given in Figure 9: Like  $\text{MoX}_2$  manifolds in the H structure, nonmagnetic semiconductors occur in  $\text{NiX}_2$  with  $X = \text{O}, \text{S}, \text{and Se}$ .  $\text{NiTe}_2$  is nonmagnetic metal in the T structure.  $\text{NiS}_2$ ,  $\text{NiSe}_2$ , and  $\text{NiTe}_2$  can occur in both the T and H structures, with the T structure being 0.2–0.5 eV energetically more favorable. However, energy band structures display significant differences by going from the T to the H structure. Whereas  $\text{NiS}_2$  and  $\text{NiSe}_2$  are nonmagnetic metals in the H structure, the same compounds are narrow and indirect-band-gap semiconductors in the T structure. Even if 3D  $\text{NbX}_2$  ( $X = \text{S}, \text{Se}, \text{and Te}$ ) can occur in the 1T and 2H structures,  $\text{NbS}_2$  and  $\text{NbTe}_2$  are stable only in the T structure. Even if  $\text{NbSe}_2$  can have both H and T structures, it is metallic in the H structure and 12 meV more energetic than the corresponding T structure. Two-dimensional and suspended  $\text{NbSe}_2$  in the H structure is of particular interest, because 3D  $\text{NbSe}_2$  is a superconductor. As for the  $\text{NiX}_2$  manifold,  $\text{VX}_2$  ( $X = \text{S}, \text{Se}, \text{and Te}$ ) compounds form both T and H structures, which have practically same cohesive energies within the accuracy limits of the numerical calculations carried out in the present study. In Figure 11, we compare the total and orbital projected densities of states of these structures. Despite the small energy differences between the T and H structures of these compounds, significant differences and striking common features in electronic structures are revealed. For example, for  $\text{VX}_2$  in the T and H structures, one recognizes differences in the densities of states. However, for both structures, the densities of states at  $E_F$  originate from V 3d states and are rather high. As for  $\text{NiX}_2$ , the character of the bands undergoes a change upon going from the T to the H structure.

**LDA +  $U$  Calculations.** It is known that electrons in transition-metal oxides are highly correlated, which, in turn, can limit the application of DFT to this class of materials. In this

**Figure 11.** Comparison of the electronic structures of specific suspended  $\text{MX}_2$  compounds forming both stable T and H structures. Total densities and orbital-projected densities of states of (a,b) 2D  $\text{VS}_2$ ,  $\text{VSe}_2$ , and  $\text{VTe}_2$  compounds and (c,d) 2D  $\text{NiS}_2$ ,  $\text{NiSe}_2$  and  $\text{NiTe}_2$  compounds in (a,c) T and (b,d) H structures. The zero of the energy is set to the Fermi level,  $E_F$ , shown by red dash-dotted line. Up and down arrows indicate spin-up and spin-down densities of states. Total densities of states are given by thick solid lines.

respect, predictions obtained using DFT on the stabilities and band gaps of  $\text{MO}_2$  compounds should be taken with caution. Surprisingly, in most cases, LDA provides reasonable predictions even for correlated systems. To model additional properties, one must take into account the double-counting terms. For this reason, all LDA +  $U$  functionals can be written as a difference of interaction terms and double-counting corrections. Even though there is a single interaction term, double-counting terms differ. Most commonly used ones for the double-counting terms are the fully localized limit (FLL) and around mean field (AMF).<sup>129</sup> The main difference between them is how they include  $U$  in the correction. The effect of  $U$  is dominant in AMF, so that it suppresses the magnetic state. For this reason, FLL is generally accepted to perform better for high-spin states, whereas AML is good for low-spin systems.

We carried out LDA +  $U$  corrections on  $\text{NiO}_2$  and  $\text{ScO}_2$  in the T structure and on  $\text{WO}_2$  in the H structure using the method introduced by Dudarev et al.<sup>71</sup> Our calculations were performed using the FFL approximation. In this method, the total energy of the system depends on  $U - J$  term, where  $U$  is the on-site Coulomb repulsion or Hubbard term and  $J$  is the exchange parameter. Because realistic values of  $U$  and  $J$  for compounds having either H or T structures are not yet available, we instead took  $U - J$  as a parameter varying between 1 and 11 eV and examined its effects on the band gap and lattice constant, as well as on the stability of  $\text{MO}_2$ . Therefore, our analysis can provide only trends in how the band gaps and lattice constants of  $\text{MO}_2$  in the H and T structures vary with  $U - J$ .

Bare LDA indicates that  $\text{ScO}_2$  has a half-metallic ground state with integer magnetic moment per unit cell. Spin-up bands have a gap between filled and unoccupied bands, whereas three spin-down bands derived from oxygen p orbitals cross the Fermi level and hence are metallic. The isosurfaces of the difference charge densities of spin-up and spin-down states suggest that the magnetic moment arises from the excess charge on O transferred from Sc atoms. Accordingly, the Hubbard  $U$  correction is taken into account for both 3d orbitals of transition-metal atom and 2p orbitals of O. Upon LDA +  $U$  calculations, two of the three metallic bands are not affected, but the energy of the third band derived from the O  $p_z$  orbital increases with increasing  $U$  energy. Eventually, the metallic spin-down bands split and open a band gap to become also semiconductor when  $(U - J) > 4$ . In addition, the size of the unit cell by up to 6% for  $(U - J) = 11$  eV.

Bare LDA predicts that both  $\text{NiO}_2$  and  $\text{WO}_2$  are non-magnetic semiconductors. The band at the edge of valence band of  $\text{NiO}_2$ , which is nondispersive around the  $\Gamma$  point, is derived mainly from 3d orbitals, whereas bands slightly below the valence band edge are derived from O 2p orbitals. In LDA +  $U$  calculations, whereas the valence band edge derived from Ni 3d orbitals is lowered with increasing  $U - J$ , the bands derived from O 2p orbitals are unaltered. At the end, the bands gap of  $\text{NiO}_2$  increases with increasing  $U - J$ . In contrast, the lattice constants and characters of the valence and conduction bands of  $\text{WO}_2$  do not change upon inclusion of the Coulomb correction term. In Figure 12, are results of our LDA +  $U$

**Figure 12.** Variations of lattice constants,  $|a| = |b|$ , and band gaps of 2D single-layer  $\text{ScO}_2$  (in the T structure),  $\text{NiO}_2$  (in the T structure), and  $\text{WO}_2$  (in the H structure) compounds with  $U - J$ .

calculations as a function of  $U - J$ . Apparently, the effect of Coulomb correlation is significant for  $\text{ScO}_2$  and  $\text{NiO}_2$  having 3d orbitals. However,  $\text{WO}_2$ , having bands derived from 5d orbitals, is not affected seriously by LDA +  $U$  calculations. Because  $\text{NiO}_2$  is always nonmagnetic no matter what the value of  $U - J$ , we would expect the same results when AMF is used. In all  $U - J$

calculations of  $\text{ScO}_2$ , we found no fluctuation of the magnetic moment, which maintained a value of  $1 \mu_B$ . Our results justify the use of the FFL approximation. Even in the case of the AML approximation, we do not think that the electronic structure of the system will change because the energy shifts in the Sc d orbital bands are not influenced strongly by the variation of  $U - J$ . The question of whether the stabilities of  $\text{MO}_2$  compounds in the H or T structure are affected after LDA +  $U$  calculations is addressed by redoing the same phonon calculations with  $U - J = 4, 8$ , and  $11 \text{ eV}$ . The stabilities of these compounds were maintained after LDA +  $U$  corrections.

## ■ DISCUSSION AND CONCLUSIONS

The unusual properties of graphene, single-layer BN, and  $\text{MoS}_2$  discovered in recent studies motivated us to explore 2D single-layer structures of transition-metal oxides and dichalcogenides,  $\text{MX}_2$  compounds, in honeycomb-like structure. Three-dimensional crystals of these  $\text{MX}_2$  compounds display diverse properties that have been the subject of several studies in the past. Recent studies have shown that 2D flakes of some  $\text{MX}_2$  compounds synthesized by various techniques have properties that could be of interest for various nanotechnology applications.  $\text{MX}_2$  compounds have a large manifold: Some members of it have layered crystals, such as  $\text{MoS}_2$  and graphite, which can allow exfoliation of single layers. We addressed the question of which compounds within this large manifold can form stable and suspended single-layer structures. In particular, we were interested in two honeycomb-like structures, namely, H and T structures. We predicted 52 different individual components that can be stable in either H and/or T structures. Specifically, these compounds can remain stable as free-standing structures, once they are synthesized in one of these single-layer structures. Our predictions were based on state-of-the-art first-principles calculations of structure optimization, phonon frequency, molecular dynamics, and mechanical properties. In addition to the extensive stability analysis, we investigated the electronic, magnetic, and mechanical properties of stable compounds. In addition to the optimized lattice constants and internal parameters, we also calculated cohesive energies  $E_C$ , formation energies  $E_f$ , magnetic moments  $\mu$ , effective charges on M and X atoms, and in-plane stiffness  $C$ . We noted various trends, generally not only in the band gap, but also in cohesive energy and in-plane stiffness (also surface polarities of semiconductors due to charge transfers from M to X), which increase with decreasing row number of X. The lattice constants exhibit a reverse trend. Finally, we found that  $\text{WO}_2$  has the highest cohesive energy, highest charge transfer from M to X, and highest in-plane stiffness among  $\text{MX}_2$  compounds in this study, suggesting that it is an important single-layer material for future studies.<sup>48</sup>

The calculated band structures reveal electronic properties that could be of interest for future nanoelectronic and sensor applications. For semiconductors, the transition from indirect to direct band gaps with decreasing number of layers has important implications. The surface polarity of semiconductors is another exceptional feature that repulsive interactions are induced quickly as soon as the separation between two parallel layers becomes smaller than the equilibrium distance. Because of their inherent surface polarity, these layers can easily stick to flat substrate surfaces and can be used as coating materials. When coated on flat surfaces as a single layer, they can modify the properties of surfaces dramatically. For example, the polar  $\text{MoS}_2$  surface was found to be water-repellant.<sup>52</sup> Our first-principles

calculations demonstrate that, in the sliding of two such surfaces, the friction coefficient and the wear are lowered dramatically. In addition, these compounds can attain important functionalities through adatom adsorption (doping) or vacancy defects. In the form of a flake or nanoribbon,  $\text{MX}_2$  compounds offer useful electronic and magnetic properties depending on whether edge atoms are saturated by hydrogen. In summary, our results show that single-layer transition-metal dioxides and dichalcogenides in honeycomb-like structures present a variety of physical and chemical properties that could be superior to those of graphene.

- (121) Before one decides that a given compound is not stable, one has to make every effort to vary specific parameters of the calculations. First, if a given compound is magnetic, spin-polarized calculations have to be carried out. In some cases, distant neighbors have to be taken into account. Calculations with relatively small superlattices might end up with instability. In other cases, it might be essential to use the correct FTT mesh to avoid ending up with fake instability. Briefly, even though phonon calculations provide a rigorous test, one has to be sure that appropriate parameters are used.
