Received: February 4, 2000; In Final Form: March 20, 2000

The reduction of HONO by HNO and NH₃ has been investigated by means of ab initio molecular orbital and transition-state theory (TST) calculations. The main reaction channels for the HNO + *trans*-HONO (*cis*-HONO) reactions are those proceeding via five-member ring transition states, leading to the production of NO and H₂O. In the temperature range 300–1000 K, TST calculations predict an A factor of 2.25 × 10¹⁰ cm³ mol⁻¹ s⁻¹ (or 3.63 × 10¹⁰ cm³ mol⁻¹ s⁻¹) and an apparent activation energy of 20.9 kcal/mol (or 21.9 kcal/mol) for the HNO + *trans*-HONO (or *cis*-HONO) reaction. In the NH₃ + HONO system, the reaction NH₃ + *cis*/trans-HONO \rightarrow H₂NNO + H₂O with barrier heights centering around 34 kcal/mol can occur at high temperatures. The reversible H-atom exchange reaction NH₃ + *cis*-HONO \rightarrow H₂NH \rightarrow C(H)NO \rightarrow NH₂H + *cis*-HONO occurs readily. The calculated rate constant for the reaction at 300 K is 1.06 × 10⁶ cm³ mol⁻¹ s⁻¹, in reasonable agreement with the experimental value of 2.2 × 10⁶ cm³ mol⁻¹ s⁻¹.

I. Introduction

It has been long known that nitrous acid (HONO) is a key reactive intermediate during the course of the chemical reactions in H/N/O-containing systems. 1-4 HONO is chemically relatively stable; it can be possibly accumulated at low temperatures. 5,6 Over the decades, the chemistry of H/N/O systems has received much attention thanks to its significant relevance to the combustion of many nitramine propellants and to the chemistry of the polluted troposphere. Accordingly, the study of HONO reactions is of great importance to our understanding of the H/N/O chemistry pertinent to the combustion of propellants and to pollution control in the troposphere.

Recently, a systematic study of HONO reactions by ab initio molecular orbital and transition-state theory (ab initio MO/TST) calculations has been performed in our laboratory. The reactions include the direct oxidation of HNO by NO₂ to produce HONO and NO, 6 the bimolecular decomposition of HONO, 7 the oxidation of HONO by NO₂ and O₃, and the reduction of HONO by HNO and NH₃. In the present paper, we report our theoretical results from the latter study. The results on the oxidation of HONO by NO₂ and O₃ will be presented in a forthcoming paper. 8

II. Computational Details

The structures of the reactants, products, intermediates, and transition states of the two title reactions have been fully optimized using the hybrid density functional B3LYP method (Becke's three-parameter nonlocal exchange functional^{9–11} with the correlation functional of Lee et al.¹²) with the 6-311G(d,p) basis set.¹³ Vibrational frequencies and zero-point energy (ZPE) corrections have been obtained at the same level of theory, and used for the subsequent TST calculations of rate constants. Each of the calculated transition states has been identified to have

one imaginary frequency. All the stationary points (transition states and adjacent local minima) along the reaction paths have been connected by using the intrinsic reaction coordinate (IRC) calculations.¹⁴ All the energies quoted and discussed in the present article include the ZPE correction.

To obtain more reliable energies, we carried out QCISD(T)/6-311G(d,p),¹⁵ restricted closed-shell and open-shell coupled cluster RCCSD(T)/6-311G(d,p),¹⁶ as well as G2M(RCC,MP2)¹⁷ calculations. The G2M(RCC,MP2) method is a modification of the Gaussian-2 (G2) approach;¹⁸ it uses B3LYP/6-311G(d,p) optimized geometries and ZPE corrections and substitutes the QCISD(T)/6-311G(d,p) calculation of the original G2 scheme by the RCCSD(T)/6-311G(d,p) calculation. The total energy in G2M(RCC,MP2) is calculated as follows:¹⁷

$$E[G2M(RCC,MP2)] = E[(RCCSD(T)/6-311G(d,p)] + \Delta E(+3df,2p) + \Delta E(HLC) + ZPE$$

where

$$\Delta E(+3df,2p) = E[MP2/6-311+G(3df,2p)] - E[MP2/6-311G(d,p)]$$

and the empirical "higher-level correction" (HLC) in millihartrees

$$\Delta E(\text{HLC}) = -5.25 \boldsymbol{n}_{\beta} - 0.19 \boldsymbol{n}_{\alpha}$$

where n_{α} and n_{β} are the numbers of α and β valence electrons, respectively.

All the ab initio calculations were performed using the GAUSSIAN94¹⁹ and MOLPRO96²⁰ programs.

III. Results and Discussion

HNO + HONO Reaction. So far, neither theoretical nor experimental work has been done on the HNO + HONO reaction. The previous ab initio and TST study of the bimolecular decomposition of HONO reveals that the reaction can proceed by a hydrogen transfer from one HONO to the O(H) atom of the second molecule accompanied by elimination of

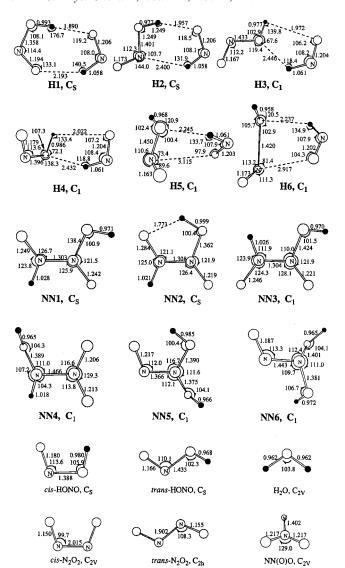

Figure 1. B3LYP/6-311G(d,p) optimized structures (bond lengths in angstroms, bond angles in degrees) of the reactants, intermediates, and products of the HNO + HONO reaction.

H₂O.⁷ It can be analogously deduced that the HNO + HONO reaction proceeds in a similar manner in that the H atom of HNO directly attacks the O(H) atom of HONO, producing H₂O and 2NO. This channel can be referred to as "direct elimination of H₂O", and can be expressed simply as

$$HNO + HONO \rightarrow H_2O + 2NO$$
 (1)

Another possible path of this reaction is the association/ elimination process:

which proceeds via a HN(O)N(O)OH intermediate. The products of this channel are H₂O and *cis*-N₂O₂, which fragments to give 2NO readily. *cis*-N₂O₂ has been known both experimentally and theoretically to be a weakly bound dimer of NO.^{21–24}

The aforementioned channels have been carefully considered in our calculations. Optimized geometries of various stable species and transition states are shown in Figures 1 and 2, respectively. Their energies are presented in Table 1.

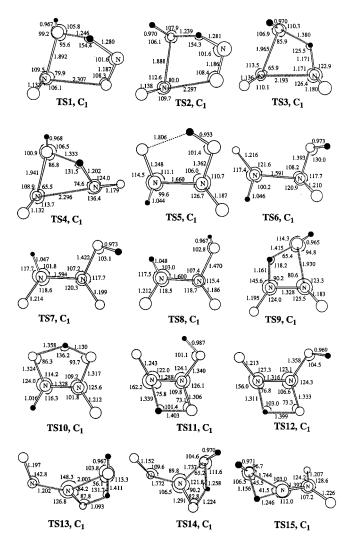

Figure 2. B3LYP/6-311G(d,p) optimized structures (bond lengths in angstroms, bond angles in degrees) of transition states of the HNO \pm HONO reaction.

Hydrogen-Bonding Complexes of HNO and HONO. HNO and HONO are polar molecules that are prone to form hydrogenbonding [ONH-O(H)NO] complexes. Our recent IRC//B3LYP/ 6-311G(d,p) study of the bimolecular decomposition of HONO²⁵ reveals that some H-bonding complexes of the reactants work as precursors for the direct H-abstraction process (i.e., the direct elimination of H₂O) in the HONO + HONO reaction system. For the present (HNO-HONO) system, we have found six H-bonding complexes in the potential energy surface. These are **H1–H6** shown in Figure 1. The predicted binding energies of these complexes range from 0.8 to 3.5 kcal/mol (Table 1) at the G2M level of theory. Among these complexes, the planar, seven-member ringlike complex, H1, which is formed by cis-HONO + HNO, is the most stable. According to the structural features of these hydrogen-bonding complexes, it can be inferred that the complexes H3, H4, H5, and H6 may be the precursors of the direct elimination of H₂O between HNO and HONO.

Direct Elimination of H_2O . The final products of this reaction channel are H_2O and 2 NO molecules. The reaction is predicted to be exothermic at all levels of theories used. The G2M-predicted exothermicity is 21.0 kcal/mol. Four transition states corresponding to the direct elimination of H_2O have been located. They are labeled as **TS1**, **TS2**, **TS3**, and **TS4** in Figure 2. **TS1** and **TS4** come from HNO + *trans*-HONO, and **TS2** and **TS3** are from HNO + *cis*-HONO. At the G2M level of theory, the barrier heights of these four transition states with

respect to the corresponding free reactants are 20.6, 21.5, 30.2, and 29.7 kcal/mol, respectively. IRC//B3LYP/6-311 G(d,p) calculations reveal that TS1, TS2, TS3, and TS4 actually derive from the 4 H-bonding complexes, that is, **H5**, **H6**, **H4**, and **H3**, respectively. This confirms the inference made in the preceding paragraph. The IRC calculations also indicate that both TS1 and TS2 lead to the direct products of $H_2O + 2NO$, whereas TS3 and TS4 result in the formation of cis-N₂O₂ and trans-N₂O₂ intermediates, respectively. It is known that trans-N₂O₂ is unstable, and cis-N2O2 is very weakly bound with a dimerization energy of 2-4 kcal/mol (experimental value^{21,22}). Our G2M calculations predict a metastable trans-N2O2, and a dimerization energy of 2.3 kcal/mol for cis-N₂O₂, in good accordance with the experimental observations.

Association—Elimination Mechanism. Topologically there should exist four isomers of N-N bonding HN(O)N(O)OH formed by the association of HNO with cis- and trans-HONO, as depicted in Scheme 1. However, only three conformers have been found in the potential energy surface (PES) of HN(O)N-(O)OH. They are NN1, NN2, and NN3 in Figure 1, corresponding to (a), (b), and (c) in the scheme. Optimization with an initial geometry like that given in Scheme 1 (c) or (d) converges to a common, nonplanar conformer, NN3. All three conformers are formed endothermically with respect to free HNO and HONO. Among these conformers, NN2 is the lowest in energy because of the existence of intramolecular hydrogen bonding. Note that the distance between the O atom of the HNO group and the H atom of the HONO group in NN2 is only 1.773 Å, even shorter

SCHEME 1

than the shortest H-bonding distance in the H-bonding [ONH-O(H)NO] complexes (1.890 Å in **H1**).

Four transition states that connect the HN(O)N(O)OH conformers and the reactants are shown in Figure 2. TS5 leads to the formation of NN2 from HNO + trans-HONO. TS6 leads to the formation of NN1 from HNO + cis-HONO. Both TS7 and TS8, which derive from cis- and trans-HONO reactions, respectively, result in NN3. At the G2M level of theory, the barrier heights for **TS5**–**TS8** are, respectively, 21.7, 25.0, 22.7, and 26.0 kcal/mol; these values are comparable with those for direct elimination of H₂O.

Among the three conformers of HN(O)N(O)OH, only NN3 can eliminate H₂O by reaction 2, whereas for NN1 and NN2, intramolecular H-transfer is required to reach a geometry that can undergo further dehydration. The dehydration of NN3 proceeds by transition state, TS9, which is higher than NN3 by

25.8 kcal/mol and higher than the HNO + trans-HONO reactants by 41.4 kcal/mol at the G2M level. For NN2, H-transfer may proceed from HONO to HNO via TS10 to the intermediate NN4 or from HNO to HONO via TS11 to NN5. The barrier height for the former process is very low (1.7 kcal/mol), whereas for the latter the barrier height is very high, 33.2 kcal/mol. The reactions from free HNO + trans-HONO to NN4 and NN5 are nearly thermoneutral, 2.7 kcal/mol for the former and 3.0 kcal/mol for the latter. For NN1, the H-transfer from HNO to HONO via TS12 results in the intermediate NN6, which is only ~1.0 kcal/mol higher than NN4 and NN5. This H-transfer process has a barrier height of 22.6 kcal/mol, but TS12 is higher than the reactants by 48.1kcal/mol. NN4, NN5, and NN6 are ready for further dehydration, as suggested by their geometries.

The dehydration of **NN4** gives rise to N=N(O)O, which is a high-energy isomer of N₂O₂. This process goes through a transition state, **TS15**, with a barrier height (46.5 kcal/mol) too high to be important; it is also highly endothermic. The dehydration of **NN5** proceeds via a transition state, **TS13**, with a barrier height of 36.1 kcal/mol, resulting in the formation of *trans*-N₂O₂. The dehydration of **NN6** also produces *trans*-N₂O₂. The corresponding transition state **TS14** has a barrier height of 34.1 kcal/mol.

All the aforementioned reaction channels are schematically shown in Figure 3. Clearly, for the reduction of HONO by HNO via HN(O)N(O)OH, it has to pass through transition states with very high barriers for the dehydration process. Accordingly, the association/elimination reaction involving HN(O)N(O)OH intermediates cannot compete effectively with the direct dehyration processes described above.

TST Calculations of Rate Constants. We have shown in our ab initio MO calculations that the key channels responsible for the HNO + HONO are those taking place by direct elimination of H₂O via hydrogen-bonding complexes. These are the reactions that go through TS1-TS4. As the barrier heights of TS3 and TS4 are higher than those of TS1 and TS2 by about 9-10 kcal/mol, we only consider the channels occurring via TS1 and TS2 in our rate constant calculations using TST.²⁶ The barrier heights calculated at the G2M level (given in Table 1) and the B3LYP/6-311G(d,p) molecular parameters of the reactants and transition states (Table 2) were used in our TST calculations. A complete summary of molecular parameters is presented in

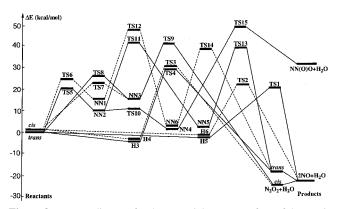

Figure 3. Energy diagram for the potential energy surface of the HNO + HONO reaction calculated in the framework of the G2M(RCC, MP2)//B3LYP/6-311G(d,p) approach. Solid lines connect the *trans*-HONO related channels; dotted lines connect the *cis*-HONO related channels.

Appendix A. We used the conventional TST method with Eckart tunneling corrections described earlier. The rate constant expressions obtained by 2- and 3-parameter fitting are presented in Table 3. For the reaction HNO + trans-HONO \rightarrow TS1 \rightarrow 2NO + H2O, 2-parameter fitting in the 300–1000 K temperature range gives an A factor of 2.55 \times 10 10 cm³ mol $^{-1}$ s $^{-1}$ and an apparent activation energy of 20.9 kcal/mol. The reaction HNO + cis-HONO \rightarrow TS2 \rightarrow 2NO + H2O is slightly slower, with an A factor of 3.63 \times 10 10 cm³ mol $^{-1}$ s $^{-1}$ and an apparent activation energy of 21.9 kcal/mol.

HONO + NH₃ Reaction. For the NH₃ + HONO reaction, the experimental work of Kaiser and Japar gave an upper limit for the rate constant ($\leq 9.04 \times 10^6 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$), 28 which is at least 4 orders slower than the NH₃ + HNO₃ reaction. Unfortunately, the products of the reaction were not clearly identified in their paper. The recent ab initio study of the bimolecular reaction of NH₃ with HNO₃ suggested the following two major channels, 29

$$NH_3 + HNO_3 \rightarrow H_2NNO_2 + H_2O$$
 (3)

$$NH_3 + HNO_3 \rightarrow H_2NONO + H_2O$$
 (4)

and predicted that both channels have approximately the same barrier, 46 kcal/mol. We expect that a similar mechanism may

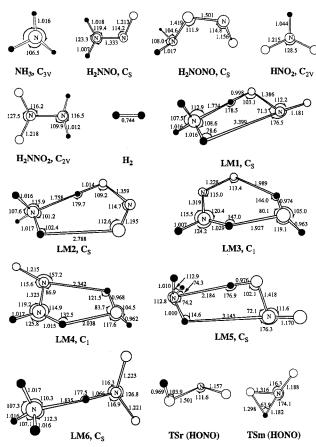

Figure 4. B3LYP/6-311G(d,p) optimized structures (bond lengths in angstroms, bond angles in degrees) of NH, intermediates, and products of the $NH_3 + HONO$ reaction.

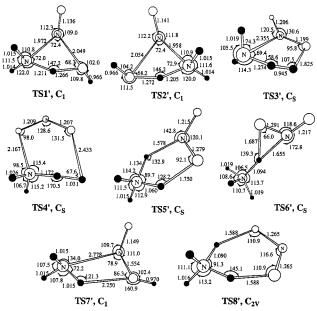

Figure 5. B3LYP/6-311G(d,p) optimized structures (bond lengths in angstroms, bond angles in degrees) of transition states of the $NH_3 + HONO$ reaction.

exist in the NH₃ + HONO reaction system, viz.

$$NH_3 + HONO \rightarrow H_2NNO + H_2O$$
 (5)

Another possible reaction may take place by H2 elimination,

$$NH_3 + HONO \rightarrow H_2NONO (or H_2NNO_2) + H_2$$
 (6

^a Relative energies in kcal/mol with respect to NH₃ + *trans*-HONO. ^b Zero-point energy corrections (kcal/mol), calculated at the B3LYP/6-311G(d,p) level. ^c Total energies are given in hartrees.

These reactions as well as the other possibilities have been carefully considered in our calculations. Optimized geometries of various species and stationary points for the NH $_3$ + HONO reaction are shown in Figures 4 and 5. The total energy of the reactants and the relative energies of the transition states, intermediates, and products calculated at the B3LYP/6-311G-(d,p) and G2M(RCC, MP2) level of theory, as well as the values of ZPE corrections are summarized in Table 4. The schematic energy diagram for the potential energy surface of the reaction under consideration is illustrated in Figure 6.

Potential Energy Surface. Our B3LYP//IRC//G2M calculations for the reaction of ammonia with nitrous acid reveal eight possible distinct pathways (\mathbf{I} - \mathbf{VIII}) that lead to the formation of four different sets of final products, $H_2NNO + H_2O$, H_2 - $NNO_2 + H_2$, $H_2NONO + H_2$, and $NH_3 + HNO_2$. They are

I.
$$NH_3 + trans$$
-HONO \rightarrow (**TS1**') \rightarrow $H_2NNO + H_2O$

II. $NH_3 + cis$ -HONO \rightarrow (**TS2**') \rightarrow $H_2NNO + H_2O$

III. $NH_3 + trans$ -HONO \rightarrow (**TS3**') \rightarrow $H_2NNO_2 + H_2$

IV. $NH_3 + cis$ -HONO \rightarrow (**TS4**') \rightarrow $H_2NONO + H_2$

V. $NH_3 + trans$ -HONO \rightarrow (**TS5**') \rightarrow $NH_3 + HNO_2$

VI. $NH_3 + trans$ -HONO \rightarrow (**TS6**') \rightarrow $NH_3 + trans$ -HONO \rightarrow (**TS7**') \rightarrow $NH_3 + cis$ -HONO

VIII. $NH_3 + trans$ -HONO \rightarrow (**TS7**') \rightarrow $NH_3 + cis$ -HONO

Let us consider these channels in detail. As can be seen from the PES presented in Figure 6, the channel I, NH₃ + trans-HONO \rightarrow LM1 \rightarrow TS1′ \rightarrow LM3 \rightarrow H₂NNO + H₂O, proceeds by abstraction of a hydrogen atom from NH₃ by the O(H) atom of trans-HONO, followed by breaking the O(H)–N bond of HONO and the association of H₂N with NO. This reaction is exothermic by 7.1 kcal/mol and has an activation barrier of 33.4 kcal/mol. Interestingly, the hydrogen-bonding intermediate,

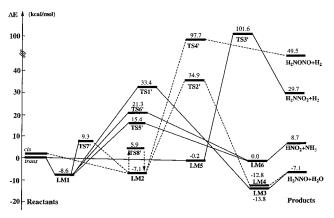

Figure 6. Energy diagram for the potential energy surface of the NH₃ + HONO reaction calculated in the framework of the G2M(RCC,-MP2)//B3LYP/6-311G(d,p) approach. Solid lines connect the *trans*-HONO related channels; dotted lines connect the *cis*-HONO related channels.

LM1, has been found to work as a precursor of the H-abstraction transition state, TS1'. Following TS1' in the reaction path, there exists another intermediate, LM3, which is a H-bonding complex of the products, $H_2NNO + H_2O$. With $NH_3 + cis$ -HONO as the reactants, we have a similar channel (II), NH₃ + cis-HONO \rightarrow LM2 \rightarrow TS2' \rightarrow LM4 \rightarrow H₂NNO + H₂O, which is exothermic by 7.5 kcal/mol. The barrier height was found to be 34.5 kcal/mol, slightly higher than that of channel I. The intermediates, LM2 and LM4, in this channel are H-bonding complexes of the reactants and the products, respectively. LM4 has a five-member ring structure with hydrogen-bonding involving H···O and H···N, whereas LM3 of channel I has a sixmember ring structure with two H···O bonds. The hydrogenbonding interaction between H₂O and H₂NNO in LM3 is stronger than that in LM4, as indicated by the lower total energy of LM3 and the shorter H···O bond lengths in LM3. Channel III, NH₃ + trans-HONO \rightarrow LM5 \rightarrow TS3' \rightarrow H₂NNO₂ + H₂, goes through a van der Waals intermediate LM5 and transition state, **TS3**'. A similar channel, **IV**, that involves *cis*-HONO via the intermediate LM2 and transition state TS4', however, leads to a different product, H2NONO. Both channels III and IV are not expected to be practically important in the NH₃ + HONO reaction, because they are sufficiently endothermic and require much higher activation energies (101.6 kcal/mol for channel III versus 97.3 kcal/mol for channel IV). Reaction channels V, $NH_3 + trans-HONO \rightarrow LM1 \rightarrow TS5' \rightarrow LM6 \rightarrow HNO_2 +$ NH₃, and VI, NH₃ + trans-HONO \rightarrow LM1 \rightarrow TS6' \rightarrow LM6 \rightarrow HNO₂ + NH₃, are endothermic by 8.6 kcal/mol; they lead to the formation of HNO2 and NH3 products via transition states TS5' and TS6', respectively. The barrier heights of channels V and VI are 15.4 and 21.3 kcal/mol, respectively. It is worth noting that both reaction channels have a common prereaction intermediate (LM1), a common postreaction intermediate (LM6), and common products. However, channel V involves H-atom exchange between NH3 and trans-HONO, whereas channel VI is an NH3-catalyzed intramolecular H-transfer process within HONO. A similar unimolecular isomerization process, trans-HONO → HNO₂, occurs via transition state, **TSm** (see Figure 4), with an activation energy of 55.2 kcal/mol (see Figure 7). [This G2M prediction is in good agreement with the previous prediction of 55.2 kcal/mol obtained by Jursic³⁰ at the B3LYP/6-311G(3df, 3dp) level of theory.] Hence, the presence of NH₃ promotes the isomerization of trans-HONO into HNO₂ by reducing the energy barrier by as much as 34 kcal/mol. Reaction channel VII, NH₃ + trans-HONO \rightarrow LM1 \rightarrow TS7' \rightarrow LM2 \rightarrow NH₃ + cis-HONO, corresponds to the trans-cis

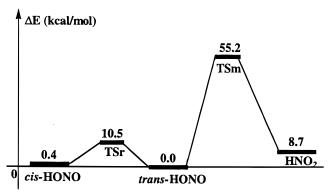

Figure 7. Energy diagram for the potential energy surface of the isomerization of an isolated HONO calculated in the framework of the G2M(RCC,MP2)//B3LYP/6-311G(d,p) approach.

isomerization of HONO in the presence of NH₃. Indeed, the transition state, TS7', is simply a H-bonding complex of NH₃ with the rotational transition state (TSr) for the trans-cis isomerization of HONO. The barrier height of this channel is 9.3 kcal/mol with respect to free $NH_3 + trans$ -HONO, and 17.9 kcal/mol with respect to LM1. For the trans—cis isomerization of an isolated HONO molecule, our G2M calculations predict a rotational transition state, **TSr** (see Figure 4), which is higher than trans-HONO by 10.5 kcal/mol (see Figure 7). It is clear that the presence of NH₃ somewhat hinders the trans-cis isomerization of HONO. Besides the aforementioned transition states (TS1'-TS7'), we also located a transition state, TS8', that connects the two equivalent isomers of LM2 in the potential energy surface of the $(NH_3 + cis-HONO)$ system. This reaction path, channel VIII, describes a reversible gas-phase reaction $NH_3 + cis$ -HONO $\Leftrightarrow NH_2H + cis$ -HONO, which was studied experimentally by infrared diode laser spectroscopy.³¹ The activation energy of this reversible exchange reaction predicted at the G2M level of theory is only 5.5 kcal/mol.

Calculation of Rate Constants. The rate constants for the NH_3 + trans-HONO reaction via TS1' (channel I) and for the NH_3 + cis-HONO reaction via TS2' (channel II) have been calculated by TST with Eckart tunneling corrections, using the activation barriers and molecular parameters given in Tables 4 and 2, respectively. A complete summary of the molecular parameters for the system is presented in Appendix B. Two-parameter fitting in the 300-1000 K temperature range gives the following Arrhenius expressions (in cm³ mol $^{-1}$ s $^{-1}$) for channels I and II:

$$k_{\rm I} = 3.16 \times 10^{10} \exp(-16800/T)$$

$$k_{\rm II} = 4.06 \times 10^{10} \exp(-17400/T)$$

with the corresponding apparent activation energies of 33.3 and 34.5 kcal/mol, respectively. The 3-parameter expressions also in $cm^3\ mol^{-1}\ s^{-1}$ fitted in the temperature range 300–3000 K are:

$$k_{\rm I} = 9.64 \times 10^{-4} \, T^{4.24} \exp(-14600/T)$$

$$k_{\rm II} = 1.08 \times 10^{-3} \, T^{4.26} \exp(-15200/T)$$

At 300 K, the calculated rate constants for the two channels are 3.36×10^{-14} and 5.62×10^{-15} cm³ mol⁻¹ s⁻¹, respectively, which are significantly lower than the upper limit reported by Kaiser and Japar,²⁸ 9 × 10⁶ cm³ mol⁻¹ s⁻¹. We have performed TST calculations for channel **VIII**, which has the lowest barrier

height. The calculated rate constant for this reversible exchange reaction at 300K is 1.06×10^6 cm³ mol⁻¹ s⁻¹, in good accordance with the experimental value of $2.2 \times 10^6 \, \text{cm}^3 \, \text{mol}^{-1}$ s⁻¹. Two-parameter fitting in the 300–1000 K temperature range gives the rate constant expression, $k_{VIII} = 1.42 \times 10^{10}$ $\exp(-2930/T)$ cm³ mol⁻¹ s⁻¹, with the apparent activation energy of 5.8 kca/mol.

IV. Concluding Remarks

The gas-phase reactions of HONO with HNO and NH₃ have been investigated using ab initio MO and TST calculations. The main reaction channels for the HNO + trans-HONO and HNO + cis-HONO reactions are those proceeding via five-memberring transition states, leading to the elimination of H₂O. The corresponding barrier heights center around 21 kcal/mol. The reaction is exothermic by 21 kcal/mol. TST calculations with tunneling corrections gave the rate constants $k_1 = 1.72 \times 10^{-3}$ $T^{4.13}\exp(-8350/T)$ and $k_2 = 1.76 \times 10^{-3} T^{4.18}\exp(-8850/T)$ cm³ mol⁻¹ s⁻¹ for the two reaction channels, respectively. Other channels that go through the HN(O)N(O)OH intermediates have been shown to require much higher activation energies for further dehydration and, therefore, are unfavorable.

In the NH₃ + HONO system, the reversible exchange reaction NH₃ + cis-HONO \leftrightarrow H₂NH-O(H)NO \leftrightarrow NH₂H + cis-HONO has the lowest activation energy, 5.5 kcal/mol. The channels leading to the production of H₂NNO and H₂O require high activation energies (33-35 kcal/mol); they may become important only at high temperatures. A TST calculation predicts the rate constant for the reversible exchange reaction to be 1.06 \times 10⁶ cm³ mol⁻¹ s⁻¹ at 300 K, in good agreement with experimental data.

Acknowledgment. This work was sponsored partially by Emory University and partially by the Caltech Multidisciplinary University Research Initiative under ONR grant no. N00014-95-1388, Program Manager Dr. J. Goldwasser. One of us (X.L.) thanks the Cherry L. Emerson Center for Scientific Computation for financial support.
